Package ‘baySeq’

April 3, 2024

Type Package
Title Empirical Bayesian analysis of patterns of differential expression in count data
Version 2.36.0
Date 2012-12-20
Depends R (>= 2.3.0), methods, GenomicRanges, abind, parallel
Imports edgeR
Suggests BiocStyle, BiocGenerics
Author Thomas J. Hardcastle
Maintainer Thomas J. Hardcastle <tjh48@cam.ac.uk>
Description
This package identifies differential expression in high-throughput 'count' data, such as that derived from next-generation sequencing machines, calculating estimated posterior likelihoods of differential expression (or more complex hypotheses) via empirical Bayesian methods.
License GPL-3

baySeq-package  Empirical Bayesian analysis of patterns of differential expression in count data.

Description

This package is intended to identify differential expression in high-throughput 'count' data, such as that derived from next-generation sequencing machines. We achieve this by empirical bayesian methods, first bootstrapping to estimate prior parameters from the data and then assessing posterior likelihoods of the models proposed.

Details
To use the package, construct a `countData` object and use the functions documented in `getPriors` to empirically determine priors on the data. Then use the functions documented in `getLikelihoods` to establish posterior likelihoods for the models proposed. A few convenience functions, `getTPs` and `topCounts` are also included.

The package (optionally) makes use of the 'snow' package for parallelisation of computationally intensive functions. This is highly recommended for large data sets.

See the vignette for more details.

References

Examples

```r
# See vignette for more examples.

# load test data
data(simData)

# replicate structure of data

# define hypotheses on data
groups <- list(NDE = c(1,1,1,1,1,1,1,1,1,1), DE = c(1,1,1,1,1,2,2,2,2,2))

# construct 'countData' object
CD <- new("countData", data = simData, replicates = replicates, groups = groups)

# estimate library sizes for countData object
libsizes(CD) <- getLibsizes(CD)

# estimate prior distributions on 'countData' object using negative binomial
# method. Other methods are available - see getPriors
```
allModels <- getModelsNB(CD, cl = NULL)

# estimate posterior likelihoods for each row of data belonging to each hypothesis
CDPost <- getLikelihoods(CDPost, cl = NULL)

# display the rows of data showing greatest association with the second
# hypothesis (differential expression)
topCounts(CDPost, group = "DE", number = 10)

# find true positive selection rate
getTPs(CDPost, group = "DE", TPs = 1:100)[1:100]

allModels

Function to generate all possible models for a countData object based on the replicate data.

Description
This function populates the '@groups' slot of the supplied countData object with all possible models for equivalence/non-equivalence of expression between replicate groups.

Usage
allModels(CD)

Arguments
CD A countData object with a populated '@replicates' slot.

Details
Given a large number of different replicate groups, the total number of possible models listed in the '@groups' slot rises exponentially. This function will attempt to list them all. The use of consensus priors (see getPriors) is recommended if the number of models is high.

Value
A countData with populated '@groups' slot.

Author(s)
Thomas J. Hardcastle

References
## Description

The `countData` class is used to define summaries of count data and establishing prior and posterior parameters on distributions defined upon the count data.

## Slots

Objects of these class contain the following components:

- **data**: Count data (matrix).
- **replicates**: The replicate structure of the data. Stored as a factor, but can be given in any form.
- **groups**: Group (model) structure to test on the data (list).
- **annotation**: Annotation data for each count (data.frame).
- **priorType**: Character string describing the type of prior information available in slot 'priors'.
- **priors**: Prior parameter information. Calculated by the functions described in `getPriors`.
- **posteriors**: Estimated (log)-posterior likelihoods for each group (matrix). Calculated by the functions described in `getLikelihoods`.
- **estProps**: Estimated proportion of tags belonging to each group (numeric). Calculated by the functions described in `getLikelihoods`.
- **nullPosts**: If calculated, the posterior likelihoods for the data having no true expression of any kind.
- **seglens**: Lengths of segments containing the counts described in data. A matrix, but may be initialised with a vector, or ignored altogether.

## Details

The `seglens` slot describes, for each row of the data object, the length of the 'segment' that contains the number of counts described by that row. For example, if we are looking at the number of hits matching genes, the `seglens` object would consist of transcript lengths. Exceptionally, we
may want to use different segment lengths for different samples and so the slot takes the form of a matrix. If the matrix has only one column, it is duplicated for all samples. Otherwise, it should have the same number of columns as the '@data' slot. If the slot is the empty matrix, then it is assumed that all segments have the same length.

Methods

The standard methods 'new', 'dim', '[', 'show', 'rbind' and 'c' have been defined for these classes. The methods 'groups', 'groups<-', 'replicates', 'replicates<-', 'libsizes' and 'libsizes<-' have also been defined in order to access and modify these slots, and their use is recommended. The method 'flatten' can be used to produce a data.frame object containing much of the basic data in a member of this class.

Author(s)

Thomas J. Hardcastle

Examples

#load test data
data(simData)

# Create a 'countData' object from test data.
groups <- list(NDE = c(1,1,1,1,1,1,1,1,1,1), DE = c(1,1,1,1,1,2,2,2,2,2))
CD <- new("countData", data = simData, replicates = replicates, groups = groups)

#estimate library sizes for countData object
libsizes(CD) <- getLibsizes(CD)

CD[1:10,]
dim(CD)

bimodalSeparator

A function that, given a numeric vector, finds the value which splits the data into two sets of minimal total variance using Otsu's method.

Description

This function takes a numeric vector and finds the value which splits the data into two sets of minimal total variance, weighted by the size of subsets (Otsu's method). It is principally intended to be a quick and easy way of separating bimodally distributed data.

Usage

bimodalSeparator(x, weights = NULL, minperc = 0.1, elbow = NULL)
Arguments

- **x**: A numeric vector containing the data to be split.
- **weights**: Possible weightings on the values in x for calculating the variance.
- **minperc**: The required minimum size of each of the two subsets, expressed as a percentage of the total size. See Details.
- **elbow**: If set, finds the 'left' or 'right' elbow of variance, instead of the minimum; defaults to NULL. See Details.

Details

This function is intended to give a quick and easy way of splitting bimodally distributed data. Where there are large outliers in the data, it may be that the value which minimises the variance does not split the bimodal data but isolates the outliers. The 'minperc' parameter can be used to ensure that each subset of the split data will be of some minimum size, avoiding the outlier problem.

If 'elbow = NULL' (the default) then the split occurs at the value that minimises the variance, x0. If 'elbow = left' then we attempt to find the elbow point to the left of the value that minimises the variance, if 'elbow = right' then we find the elbow point to the right of the value that minimises the variance. Elbow points are found by drawing a line from the first point (for the left elbow) or the last point (for the right elbow) to x0, and finding the location on the curve of summed variances which maximises the distance to that line.

Value

Numeric value which splits the data.

Author(s)

Thomas J. Hardcastle

Examples

```r
bimodalSeparator(c(rnorm(200, mean = c(5,7), sd = 1)))
```

Description

This 'countData' object is derived from the data set 'simData' and contains the estimated likelihoods of differential expression. This data set is intended to be used to speed the processing of the examples.

Usage

CDPost
Format

A ‘countData’ object.

Source

Simulation.

References

```
CDPriors ...
'countData' object derived from data file 'simData' with estimated priors.
```

Description

This ‘countData’ object is derived from the data set ‘simData’ and contains the estimated priors. This data set is intended to be used to speed the processing of the examples.

Usage

CDPriors

Format

A ‘countData’ object.

Source

Simulation.

densityFunction-class

Class "densityFunction"

Description
This function fills the '@densityFunction' slot of a 'countData' object. It defines the distribution used to estimate posterior likelihoods, and associated values used in these calculations.

Objects from the Class
Objects can be created by calls of the form new("densityFunction", ...).

Slots

description: A description of the distribution defined.
density: A "function", defining the likelihood of a data array given observed data and hyperparameters.
initiatingValues: A "list" of functions (may be supplied as numerics) that define initial values of numeric prior discovery.
equalOverReplicates: A "logical", describing which of the hyperparameters are equally marginally distributed over all groups, and which are not.
lower: A "function", required to define the lower limit of optimisation in the case where only one hyperparameter is *not* equally marginally distributed over all groups.
upper: A "function", required to define the upper limit of optimisation, as for 'lower', above.
stratifyFunction: An optional "function", used to stratify the data for more accurate prior estimation.
stratifyBreaks: An optional "numeric", used to define the number of strata in a stratification.
nullFunction: An optional "function" on the hyperparameters, used to generate a one-dimensional distribution which can be partitioned to identify 'null' data.
orderingFunction: An optional "function" for ordering the data between groups of a model.
modifyNullPriors: An optional "function" for modifying the priors for the 'null' data.

Methods
No methods defined with class "densityFunction" in the signature.

Author(s)
Thomas J. Hardcastle

Examples
showClass("densityFunction")
densityFunctions

Lists all currently available densityFunctions.

Description

The densityFunction objects define the distribution and various other parameters used to analyse the data stored in a countData object.

Usage

densityFunctions()

Value

Character string giving names of available densityFunction objects.

Author(s)

Thomas J. Hardcastle

References

densityFunction

getLibsizes

Estimates library scaling factors (library sizes) for count data.

Description

This function estimates the library scaling factors that should be used for either a 'countData', or a matrix of counts and replicate information.

Usage

getLibsizes(cD, data, replicates, subset = NULL, estimationType = c("quantile", "total", "edgeR"), quant...
getLibsizes

Arguments

cD A countData object.
data A matrix of count values. Ignored if `cD` is given.
replicates A replicate structure for the data given in `data`. Ignored if `cD` is given.
subset A numerical vector indicating the rows of the `countData` object that should be used to estimate library scaling factors.
estimationType One of `quantile`, `total`, or `edgeR`. Partial matching is allowed. See Details.
quantile A value between 0 and 1 indicating the level of trimming that should take place. See Details.
... Additional parameters to be passed to the `edgeR` calcNormFactors function.

Details

This function estimates the library scaling factors (surrogates for library size) in one of several ways, depending on the `estimationType` argument. `total` will give the library sizes by summing all counts in each sample. `quantile` will give a library scaling factor by the method of Bullard et al (Bioinformatics 2010), summing all counts in each sample whose value below the qth quantile of non-zero counts for that sample. `edgeR` uses the Trimmed Mean of M-vaes (TMM) method of Robinson & Oshlack (Genome Biology, 2010) via the `edgeR` calcNormFactors function; other options are available through this function.

If a countData object `cD` is given, the library sizes will be inferred from this. Alternatively, a matrix of count values (columns are libraries) and a replicate structure (a vector defining which samples belong to which replicate group) can be given.

Value

If a `countData` object is given, an identical object will be returned with updated library sizes. If only the data and replicate structure are given, a numerical vector of library sizes (scaling factors) for each library in the data will be returned.

replicates <- c(1,1,1,1,1,2,2,2,2,2)
groups <- list(c(1,1,1,1,1,1,1,1,1,1), c(1,1,1,1,1,2,2,2,2,2))
CD <- new("countData", data = simData, replicates = replicates, groups = groups)

libsizes(CD) <- getLibsizes(CD)
getLikelihoods

Finds posterior likelihoods for each count or paired count as belonging to some model.

Description

These functions calculate posterior probabilities for each of the rows in a `countData` object belonging to each of the models specified in the `groups` slot.

Usage

```r
getLikelihoods.NB(cD, prs, pET = "BIC", marginalise = FALSE, subset = NULL,
priorSubset = NULL, bootStraps = 1, conv = 1e-4, nullData = FALSE,
returnAll = FALSE, returnPD = FALSE, verbose = TRUE, discardSampling = FALSE, cl, ...)
getLikelihoods.BB(cD, prs, pET = "BIC", marginalise = FALSE, subset = NULL,
priorSubset = NULL, bootStraps = 1, conv = 1e-04, nullData = FALSE,
returnAll = FALSE, returnPD = FALSE, verbose = TRUE, discardSampling = FALSE, cl, ...)
getLikelihoods(cD, prs, pET = "BIC", marginalise = FALSE, subset = NULL,
priorSubset = NULL, bootStraps = 1, bsNullOnly = TRUE, conv = 1e-4, nullData = FALSE,
weightByLocLikelihoods = TRUE, modelPriorSets = list(), modelPriorValues = list(),
returnAll = FALSE, modelLikes = TRUE, returnPD = FALSE, verbose = TRUE, discardSampling = FALSE, cl = NULL, tempFile = NULL, largeness = 1e+08)
```

Arguments

- **cD**: An object of type `countData`, or descending from this class.
- **prs**: (Initial) prior probabilities for each of the groups in the `cD` object. Should sum to 1, unless `nullData` is `TRUE`, in which case it should sum to less than 1.
- **pET**: What type of prior re-estimation should be attempted? Defaults to "BIC"; "none" and "iteratively" are also available.
- **marginalise**: Should an attempt be made to numerically marginalise over a prior distribution iteratively estimated from the posterior distribution? Defaults to `FALSE`, as in general offers little performance gain and increases computational cost considerably.
- **subset**: Numeric vector giving the subset of counts for which posterior likelihoods should be estimated.
- **priorSubset**: Numeric vector giving the subset of counts which may be used to estimate prior probabilities on each of the groups. See Details.
- **bootStraps**: How many iterations of bootstrapping should be used in the (re)estimation of priors in the negative binomial method.
- **bsNullOnly**: If `TRUE` (default, bootstrap hyper-parameters based on the likelihood of the null model and its inverse only; otherwise, on the likelihood of all models).
The `getLikelihoods` function estimates, under the assumption of various distributions, the (log) posterior likelihoods that each count belongs to a group defined by the `@group` slot of the input object. The posterior likelihoods are stored on the natural log scale in the `@posteriors` slot of the `countData` object generated by this function. This is because the posterior likelihoods are calculated in this form, and ordering of the counts is better done on these log-likelihoods than on the likelihoods.

If `pET = "none"` then no attempt is made to re-estimate the prior likelihoods given in the `prs` variable. However, if `pET = "BIC"`, then the function will attempt to estimate the prior likelihoods by using the Bayesian Information Criterion to identify the proportion of the data best explained by...
each model and taking these proportions as prior. Alternatively, an iterative re-estimation of priors is possible (‘pET = “iteratively”’), in which an initial estimate for the prior likelihoods of the models is used to calculate the posteriors and then the priors are updated by taking the mean of the posterior likelihoods for each model across all data. This often works well, particularly if the 'BIC' method is used (see Hardcastle & Kelly 2010 for details). However, if the data are sufficiently non-independent, this approach may substantially mis-estimate the true priors. If it is possible to select a representative subset of the data by setting the variable ‘subsetPriors’ that is sufficiently independent, then better estimates may be acquired.

In certain circumstances, it may be expected that certain subsets of the data are likely to behave differently to others; for example, if a set of genes are expected in advance to be differentially expressed, while the majority of the data are not. In this case, it may be advantageous (in terms of improving false discovery rates) to specify these different subsets in the modelPriorSets variable. However, care should be taken downstream to avoid confirmation bias.

Filtering the data may be extremely advantageous in reducing run time. This can be done by passing a numeric vector to 'subset' defining a subset of the data for which posterior likelihoods are required. See Hardcastle & Kelly (2010) for a definition of the negative binomial methods.

A `cluster` object is strongly recommended in order to parallelise the estimation of posterior likelihoods, particularly for the negative binomial method. However, passing NULL to the `cl` variable will allow the functions to run in non-parallel mode.

The `getLikelihoods.NB` and `getLikelihoods.BB` functions are now deprecated and will soon be removed.

**Value**

A `countData` object.

**getPosteriors**

An internal function in the baySeq package for calculating posterior likelihoods given likelihoods of the data.

**Description**

For likelihoods of the data given a set of models, this function calculates the posterior likelihoods of the models given the data. An internal function of baySeq, which should not in general be called by the user.

**Usage**

generateseconds(ps, prs, pET = "none", marginalise = FALSE, groups, priorSubset = NULL, maxit = 100, accuracy = 1e-5, eqOverRep = NULL, cl = cl)
Arguments

- **ps**: A matrix containing likelihoods of the data for each count (rows) under each model (columns).
- **prs**: (Initial) prior probabilities for each of the models.
- **pET**: What type of prior re-estimation should be attempted? Defaults to "none"; "BIC" and "iteratively" are also available.
- **marginalise**: Should an attempt be made to numerically marginalise over a prior distribution iteratively estimated from the posterior distribution? Defaults to FALSE, as in general offers little performance gain and increases computational cost considerably.
- **groups**: Group structure from which likelihoods in `ps` were defined.
- **priorSubset**: If 'estimatePriors = TRUE', what subset of the data should be used to re-estimate the priors? Defaults to NULL, implying all data will be used.
- **maxit**: What is the maximum number of iterations that should be tried if we are bootstrapping prior probabilities from the data?
- **accuracy**: How small should the difference in estimated priors be before we stop bootstrapping.
- **eqOverRep**: A boolean describing which prior values are equally marginally distributed over replicates.
- **cl**: Parallelisation cluster object.

Details

An internal function, that will not in general be called by the user. It takes the log-likelihoods of the data given the models being tested and returns the posterior likelihoods of the models.

The function may attempt to estimate the prior likelihoods either by using the Bayesian Information Criterion ("pET = "BIC") to identify the proportion of the data best explained by each model and taking these proportions as prior. Alternatively, an iterative re-estimation of priors is possible ("pET = "iteratively"), in which an initial estimate for the prior likelihoods of the models is used to calculated the posteriors and then the priors are updated by taking the mean of the posterior likelihoods for each model across all data.

Value

A list containing posteriors: estimated posterior likelihoods of the model for each count (log-scale) and priors: estimated (or given) prior probabilities of the model.

Author(s)

Thomas J. Hardcastle

References

**getPriors**

Estimates prior parameters for the underlying distributions of 'count' data.

**Description**

These functions estimate, via maximum likelihood methods, the parameters of the underlying distributions specified in the 'densityFunction' slot of the countData object. A special case is maintained for historical reasons; getPriors.NB estimates parameters for a negative binomial distribution using quasi-maximum-likelihood methods.

**Usage**

```r
getPriors(cD, samplesize = 1e5, samplingSubset = NULL, consensus = FALSE, cl, verbose = TRUE)
getPriors.NB(cD, samplesize = 1e5, samplingSubset = NULL, equalDispersions = TRUE, estimation = "QL", verbose = TRUE, zeroML = FALSE, consensus = FALSE, cl, ...)```

**Arguments**

- `cD` A `countData` object.
- `samplesize` How large a sample should be taken in estimating the priors?
- `samplingSubset` If given, the priors will be sampled only from the subset specified.
- `consensus` If TRUE, creates a consensus distribution rather than a separate distribution for each member of the groups structure in the ‘cD’ object. See Details.

**Examples**

```r
# Simulate some log-likelihoods of data given models (each model
# describes one column of the 'ps' object).
ps <- log(rbind(
    cbind(runif(10000, 0, 0.1), runif(10000, 0.3, 0.9)),
    cbind(runif(10000, 0.4, 0.9), runif(1000, 0, 0.2))))

# get posterior log-likelihoods of model, estimating prior likelihoods
# of each model from the data.
pps <- getPosteriors(ps, prs <- c(0.5, 0.5), pET = "none", cl = NULL)

pps$priors
pps$posteriors[1:10,]
```
**cl** A SNOW cluster object.

**verbose** Should status messages be displayed? Defaults to TRUE.

**equalDispersions** Should we assume equal dispersions of data across all groups in the 'cD' object? Defaults to TRUE; see Details.

**estimation** Defaults to 'QL', indicating quasi-likelihood estimation of priors. Currently, the only other possibilities are "ML", a maximum-likelihood method, and "edgeR", the moderated dispersion estimates produced by the 'edgeR' package. See Details.

**zeroML** Should parameters from zero data (rows that within a group are all zeros) be estimated using maximum likelihood methods (which will result in zeros in the parameters)? See Details.

... Additional parameters to be passed to the `estimateTagwiseDisp` function if 'estimation = "edgeR"'.

### Details

These functions empirically estimate prior parameters for the distributions used in estimating posterior likelihoods of each count belonging to a particular group.

For priors estimated for the negative binomial methods, three options are available. Differences in the options focus on the way in which the dispersion is estimated for the data. In simulation studies, quasi-likelihood methods ('estimation = "QL"') performed best and so these are used by default. Alternatives are maximum-likelihood methods ('estimation = "ML"'), and the 'edgeR' packages moderated dispersion estimates ('estimation = "edgeR"').

The priors estimated for the negative binomial methods ('getPriors.NB') may assume that the dispersion of data for a given row is identical for all group structures defined in 'cD@groups' ('equalDispersions = TRUE'). Alternatively, the dispersions may be estimated individually for each group structure ('equalDispersions = FALSE'). Unless there is a strong reason for believing that the data are differently dispersed between groups, 'equalDispersions = TRUE' is recommended. If 'estimation = "edgeR"' then this parameter is ignored and dispersion is assumed identical for all group structures.

If all counts in a given row for a given group are zero, then maximum and quasi-likelihood estimation methods will result in a zero parameter for the mean. In analyses where segment length is a factor, this makes it hard to differentiate between (for example) a region which contains no reads but is only ten bases long and one which likewise contains no reads but is ten megabases long. If 'zeroML' is FALSE, therefore, the dispersion is set to 1 and the mean estimated as the value that leaves the likelihood of zero data at fifty percent.

If 'consensus = TRUE', then a consensus distribution is created and used for each group in the 'cD' object. This allows faster computation of the priors and likelihoods, but with some degradation of accuracy.

A 'cluster' object is recommended in order to estimate the priors for the negative binomial distribution. Passing NULL to this variable will cause the function to run in non-parallel mode.

### Value

A `countData` object.
getTPs

CDPriors <- getPriors.NB(CD, samplesize = 10^5, estimation = "QL", cl = c1)

getTPs

Gets the number of true positives in the top \( n \) counts selected by ranked posterior likelihoods
Description

If the true positives are known, this function will return a vector, the ith member of which gives the number of true positives identified if the top i counts, based on estimated posterior likelihoods, are chosen.

Usage

getTPs(cD, group, decreasing = TRUE, TPs)

Arguments

cD          countData object, containing posterior likelihoods for each group.
group       Which group should we give the counts for? See Details.
decreasing  Ordering on posterior likelihoods.
TPs          Known true positives.

Details

In the rare (or simulated) cases where the true positives are known, this function will calculate the number of true positives selected at any cutoff.

The 'group' can be defined either as the number of the element in 'cD@groups' or as a string which will be partially matched to the names of the 'cD@groups' elements. If group = NULL, then the function looks at the posterior likelihoods that the data have no true differential expression (if calculated).

Value

A vector, the ith member of which gives the number of true positives identified if the top i counts are chosen.

getTPs(CDPost, group = "DE", decreasing = TRUE, TPs = 1:100)

makeOrderings  Construct orderings for count data given a model structure and an
          ordering function.

Description

Given a model structure as defined in the '@groups' slot of a countData object containing more
than one group, it is often possible to define an ordering on the groups for a given genomic event.
To take a simple example, if the average expression of a gene is higher in sample set A then in
sample set B, then we might impose an ordering A>B.

Usage

makeOrderings(cD, orderingFunction)

Arguments

cD          A countData object, or a descendant thereof.
orderingFunction          A function defining the orderings. If not given, will be taken from the '@densityFunction' slot of 'cD'. See Details, and examples below.

Details

The orderingFunction takes 'dat' and 'observables' as arguments. 'dat' is equivalent to the '@data'
slot of the 'cD' object, and 'observables' the combined data in the '@sampleObservables', '@rowObservables' and '@cellObservables' slots.

Value

A countData with populated '@orderings' slot.

Examples

```r
# load test data
data(simData)

# Create a countData object from test data
groups <- list(NDE = c(1,1,1,1,1,1,1,1), DE = c(1,1,1,1,1,2,2,2))
CD <- new("countData", data = simData, replicates = replicates, groups = groups)
libsizes(CD) <- getLibsizes(CD)

# order on expression normalised for library size (scaling factor) and gene length
CD <- makeOrderings(CD, orderingFunction = function(dat, observables) dat / observables$libsizes)

# orderings calculated for DE group
head(CD@orderings)

# load test (paired) data
data(pairData)

# create a countData object from paired data
pairCD <- new("countData", data = list(pairData[,1:4], pairData[,5:8]),
replicates = c(1,1,2,2),
groups = list(NDE = c(1,1,1,1), DE = c(1,1,2,2)),
densityFunction = bbDensity)
libsizes(pairCD) <- getLibsizes(pairCD)

# order on (log-)ratio of pairs, with fudge-factor on zeros.
pairCD <- makeOrderings(pairCD, orderingFunction = function(dat, observables) {
  data <- dat / observables$libsizes
  adjmin <- min(data[data > 0]) / 10
  log(data[,1] + adjmin) - log(data[,2] + adjmin)
})

# orderings calculated for DE group
head(pairCD@orderings)
```

---

**marginaliseEqual**

*Computes marginal likelihoods that two replicate groups are equal.*

**Description**

In cases where multiple models are simultaneously evaluated in the 'getLikelihoods' function, the posterior likelihoods for each model in which two conditions are equivalent can be summed to give the marginal likelihood of equivalence for all biomolecular events (i.e., data rows).
marginaliseEqual

Usage

marginaliseEqual(cD, r1, r2)

Arguments

cD A countData object with evaluated posterior likelihoods in the '@posteriors' slot.
r1 A defined group name to identify in the '@groups' slot of the countData object 'cD'.
r2 A defined group name to identify in the '@groups' slot of the countData object 'cD'.

Value

A vector of marginal posterior likelihoods defining the probability that the two group identifiers are equal for each row of the data.

Author(s)

Thomas J. Hardcastle

See Also

allModels marginalisePairwise

Examples

# load test data
data(simData)

# Create a (countData) object from test data, supposing that there are
# multiple experimental groups present.
CD <- new("countData", data = simData, replicates = replicates)
CD <- allModels(CD)

# The total number of models generated is high.
length(CD@groups)

# Priors and likelihoods acquired through standard means.
## Not run: CD <- getPriors(CD, cl = cl)
## Not run: CD <- getLikelihoods(CD, cl = cl)

# Marginal likelihood that 'simA' and 'simD' replicate groups are equal
# for each row of the data.
## Not run: marginaliseEqual(CD, "simA", "simD")
marginalisePairwise

Computes marginal likelihoods that two replicate groups differ, in a particular direction.

Description

In cases where multiple models are simultaneously evaluated in the 'getLikelihoods' function, the posterior likelihoods for each model in which one condition is greater than another can be summed to give the marginal likelihood of (directed) difference for all biomolecular events (i.e., data rows).

Usage

marginalisePairwise(cD, greaterThan, lessThan)

Arguments

cD
A countData object with evaluated posterior likelihoods in the '@posteriors' slot.

greaterThan
A defined group name (or vector of group names) to identify in the '@groups' slot of the countData object 'cD'; the function will identify all models in which these groups are equivalent and greater than that defined in the 'lessThan' variable.

lessThan
A defined group name (or vector of group names) to identify in the '@groups' slot of the countData object 'cD'; the function will identify all models in which these groups are equivalent and less than that defined in the 'greaterThan' variable.

Value

A vector of marginal posterior likelihoods defining the probability that the two group identifiers are (directionally) different for each row of the data.

## Not run: CD <- getLikelihoods(CD, cl = cl)

# Marginal likelihood that 'simA' condition is greater than 'simD' group
# for each row of the data.
## Not run: marginalisePairwise(CD, "simA", "simD")

methObservables Generation of intermediate values in likelihood estimation for methylation data.

Description
Estimating prior and posterior values for methylation data that account for non-conversion rates is a time-consuming process. Significant increases in speed can be made by calculating in advance sets of data that will be re-used at several points of these analyses. This function populates the '@cellObservables' slot of a 'countData' object that contains a 'nonconversion' object in the '@sampleObservables' slot.

Usage
methObservables(mD, tail = 0.01)

Arguments
mD A countData object, or descendant, which contains a numeric vector 'nonconversion' in the '@sampleObservables' slot.
tail A cutoff on the quantile (upper and lower) of the distribution on the non-conversion. Smaller values will give a marginal increase in accuracy at high computational cost. Large values will decrease accuracy somewhat but reduce the time needed for analysis. See Details.

Details
For loci with large numbers of observed cytosines, the full dataset to be pre-computed will be very large. However, only the pre-computations near the average expression level will contribute significantly to the estimated priors and posteriors. The 'tail' parameter sets the quantile at which the distribution is considered to no longer contribute significantly to the results. Values below 0.1 are probably acceptable under nearly all circumstances.
**Value**

A `countData` object with the `@cellObservables` slot populated with temporary values useful in the faster calculation of likelihoods.

**Author(s)**

Thomas J. Hardcastle

---

**mobAnnotation**

*Annotation data for a set of small RNA loci derived from sequencing of grafts of Arabidopsis thaliana intended for differential expression analyses.*

**Description**

This data set is a data.frame (‘mobAnnotation’) describing three thousand small RNA loci identified in a set of Arabidopsis grafting experiments.

The data acquired through sequencing for these loci is found in data file ‘mobData’.

**Usage**

`mobAnnotation`

**Format**

A data.frame defining chromosome and position of the sRNA loci.

**Source**

Illumina sequencing.

**References**

**See Also**

`mobData`
### Description

This data set is a matrix (`mobData`) of counts acquired for three thousand small RNA loci from a set of Arabidopsis grafting experiments. Three different biological conditions exist within these data; one in which a Dicer 2,3,4 triple mutant shoot is grafted onto a Dicer 2,3,4 triple mutant root (SL236 and SL260), one in which a wild-type shoot is grafted onto a wild-type root (SL239 and SL240), and one in which a wild-type shoot is grafted onto a Dicer 2,3,4 triple mutant root (SL237 and SL238). Dicer 2,3,4 is required for the production of 22nt and 24nt small RNAs, as well as some 21nt ones. Consequently, if we detect differentially expressed sRNA loci in the root stock of the grafts, we can make inferences about the mobility of small RNAs.

The annotation of the loci from which these data derive is in data file `mobAnnotation`.

### Usage

`mobData`

### Format

A matrix of which each of the six columns represents a sample, and each row an sRNA locus (acquired by sequencing).

### Source

Illumina sequencing.

### References

### See Also

`mobAnnotation`
Description

This data set is a matrix (‘pairData’) of simulated counts from a set of high-throughput sequencing data from a paired experimental design. The first four columns of data are to be paired with the second four columns of data respectively. The first two paired samples form one replicate group, the second two paired samples form another replicate group. The first hundred rows of the data are truly differentially expressed between replicate groups, the second hundred are differentially expressed between pairs, the remainder have no differential expression.

It is simulated according to a set of Poisson distributions whose parameters for each row are determined by a beta distribution on the relative proportions of data in each pairing.

Usage

pairData

Format

A matrix of which each of the eight columns represents a sample, and each row some discrete data (acquired by sequencing).

Source

Simulation.

plotMA.CD

'MA'-plot for count data.

Description

This function creates an MA-plot from two sets of samples. For those data where the log-ratio is infinite (because in one set of sample data all observed counts are zero), we plot instead the log-values of the other group.

Usage

plotMA.CD(cD, samplesA, samplesB, normaliseData = TRUE, scale = NULL, xlab = "A", ylab = "M", ...)
Arguments

- **cD**: A `countData` object.
- **samplesA**: Either a character vector, identifying sample set A by either replicate name or sample name, or a numerical vector giving the columns of data in the `countData` object that forms sample set A. See Details.
- **samplesB**: Either a character vector, identifying sample set B by either replicate name or sample name, or a numerical vector giving the columns of data in the `countData` object that forms sample set B. See Details.
- **normaliseData**: Should the data be normalised by library size before computing log-ratios? Defaults to TRUE.
- **scale**: If given, defines the scale on which the log-ratios will be plotted. Defaults to NULL, implying that the scale will be calculated by the function.
- **xlab**: Label for the X-axis. Defaults to "A".
- **ylab**: Label for the Y-axis. Defaults to "M".
- **...**: Any other parameters to be passed to the `plot` function.

Details

The samples sets can be identified either by a numeric vector which specifies the columns of data from the `countData` object `cD`, or by a character vector. If a character vector is used, the members of the character vector will first be searched for in the `@replicates` slot of the `cD` object. Any members of the vector not found in the replicates slot, will be searched for in the column names of the `@data` slot of the `cD` object. Different classes of vector can be used for `samplesA` and `samplesB`, as shown in the example below.

Value

Plotting function.

`countData`

Examples

data(simData)
groups <- list(NDE = c(1,1,1,1,1,1,1,1), DE = c(1,1,1,1,2,2,2,2))
CD <- new("countData", data = simData, replicates = replicates, groups = groups)

#estimate library sizes for countData object
libsizes(CD) <- getLibsizes(CD)
# MA-plot comparing replicate groups
plotMA.CD(CD, samplesA = "simA", samplesB = 6:10)

---

## plotNullPrior

**Plots distribution of null function and shows the threshold separator.**

### Description

In sequencing expression of various genomic events, it is not uncommon to find a subset of genomic events that are qualitatively different from the remainder of the data. Thus, for some function of the estimated priors, we may observe bimodality or long tails which correlate to this subset.

### Usage

```
plotNullPrior(cD, ...)
```

### Arguments

- **cD**
  - A `countData` object with a `@nullFunction` slot in its `@densityFunction`.
- **...**
  - Additional arguments to be passed to `plot`

### Value

Invisibly, the numeric value of the threshold.

### Author(s)

Thomas J. Hardcastle

---

## plotPosteriors

**Plots the posterior likelihoods estimated for a `countData` object against the log-ratios observed between two sets of sample data.**

### Description

This function plots the posterior likelihoods estimated for a `countData` object against the log-ratios observed between two sets of sample data. For those data where the log-ratio is infinite (because in one set of sample data all observed counts are zero), we plot instead the log-values of the other group.

### Usage

```
plotPosteriors(cD, group, samplesA, samplesB, ...)
```
Arguments

- **cD**: A `countData` object, for which posterior likelihoods have been estimated (see `getPosteriors`).
- **group**: From which group (as defined in the `cD@groups` slot) should posterior likelihoods be shown? Can be defined either as the number of the element in `cD@groups` or as a string which will be partially matched to the names of the `cD@groups` elements.
- **samplesA**: A numerical vector giving the columns of data in the `countData` object that forms sample set A.
- **samplesB**: A numerical vector giving the columns of data in the `countData` object that forms sample set B.
- **...**: Any other parameters to be passed to the `plot` function.

Value

Plotting function.

- `getPosteriors`

Examples

```r
# We load in a `countData` object containing the estimated posterior
# likelihoods of expression (see `getLikelihoods`).

data(CDPost)

plotPosteriors(CDPost, group = "DE", samplesA = 1:5, samplesB = 6:10)

# equivalent to plotPosteriors(CDPost, group = 2, samplesA = 1:5, samplesB = 6:10)
```

---

**plotPriors**

Plots the density of the log values estimated for the mean rate in the prior data for the Negative Binomial approach to detecting differential expression

Description

This function plots the density of the log values estimated for the mean rate in the data used to estimate a prior distribution for data under the assumption of a Negative Binomial distribution. This function is useful for looking for bimodality of the distributions, and thus determining whether we should try and identify data with no true expression.
Usage
plotPriors(cD, group, par = 1)

Arguments
cD countData object, for which priors have been estimated using the assumption of a Negative Binomial distribution (see getPriors.NB).
group Which group should we plot the priors for? In general, should be the group that defines non-differentially expressed data. Can be defined either as the number of the element in 'cD@groups' or as a string which will be partially matched to the names of the 'cD@groups' elements.
par The parameter of the prior that will be plotted.

Details
If the plot of the data appears bimodal, then it may be sensible to try and look for data with no true expression by using the option nullPosts = TRUE in getLikelihoods.NB.

Value
Plotting function.

Author(s)
Thomas J. Hardcastle

getriors.NB, getLikelihoods.NB

Examples
# We load in a 'countData' object containing the estimated priors (see 'getPriors').
data(CDPriors)
plotPriors(CDPriors, group = "NDE", par = 1)

selectTop
Selects the top genomic events, based on posterior likelihoods, from a 'countData' object.

Description
This function subsets a countData object by selecting those events that best (or least) represent a model, based on the posterior likelihoods estimated for that model and some threshold. Selection can be done for a specific model (and ordering of the data under that model) or for all models (and all orderings).
Usage

```r
selectTop(cD, group, ordering, orderings = TRUE, decreasing = TRUE,
number = 10, likelihood, FDR, FWER, posteriors)
```

Arguments

- `cD`: A `countData` object, with a populated ‘@posteriors’ slot (unless ‘posteriors’ is specified; see below).
- `group`: Optionally, the model of interest, as defined in the ‘@groups’ slot of the `countData` object. If unspecified, subsets for all models will be returned as a list.
- `ordering`: If ‘group’ is specified, a particular ordering of the data based on that group can also be specified.
- `orderings`: If no group is specified, should the selection of models also be split by the orderings of the data under the models? Defaults to TRUE.
- `decreasing`: If FALSE, considers the data with the lowest posterior likelihoods, rather than the greatest (i.e., selects those data least likely to conform to a particular model.
- `number`: If given, selects the top ‘number’ of genomic events for each model (and optionally, ordering). Ignored if another selection criteria is chosen, unless this criteria would return no values.
- `likelihood`: If given, selects all genomic events for a given model (and optionally, ordering) with posterior likelihood exceeding this value.
- `FDR`: If given, selects all genomic events for a given model (and optionally, ordering) with false discovery rate below this value. Ignored if likelihood is specified.
- `FWER`: If given, selects all genomic events for a given model (and optionally, ordering) with family-wise error rate below this value. Ignored if likelihood or FDR is specified.
- `posteriors`: If given, a vector of log-posterior likelihoods to use instead of those in the ‘@posteriors’ slot of the ‘cD’ object.

Value

Either a single `countData` object (if ‘group’ is specified), or a named list of `countData` objects.

selectTop(CDPost, FDR = 0.01)

---

simData  
*Simulated data for testing the baySeq package methods*

**Description**

This data set is a matrix (‘simData’) of simulated counts from a simple pairwise expression analysis. It is simulated according to a negative binomial distribution with varying parameters for each row. The first hundred rows of the data are truly differentially expressed, the remainder have no differential expression.

**Usage**

simData

**Format**

A matrix of which each of the ten columns represents a sample, and each row some discrete data (acquired by sequencing).

**Source**

Simulation.

**References**

---

summarisePosteriors  
*Summarises expected number of genomic events given the calculated posterior likelihoods of a countData object.*

**Description**

Given posterior likelihoods for each model, we can calculate the expected number of genomic events corresponding to each model (and to each ordering within each model) by summing the posterior likelihoods.

**Usage**

summarisePosteriors(cD, orderings = TRUE)
topCounts

Arguments

cD    A countData object.
orderings Indicates whether models should be split by orderings of the data under the model (defaults to TRUE).

Value

Numeric vector of expected number of genomic events belonging to each model (optionally, split by orderings).

Author(s)

Thomas J. Hardcastle

See Also

topCounts, selectTop

Examples

# We load in a `countData` object containing the estimated posterior likelihoods of expression (see `getLikelihoods`).

data(CDPost)

# summarise the expected number of genomic events in each category
summarisePosteriors(CDPost)

topCounts

Get the top counts corresponding to some group from a `countData` object

Description

Takes posterior likelihoods and returns the counts with highest (or lowest) likelihood of association with a given group.

Usage

topCounts(cD, group, ordering, decreasing = TRUE, number = 10, likelihood, FDR, FWER, normaliseData = FALSE, posteriors)
Arguments

- **cD** - `countData` object, containing posterior likelihoods for each group (unless 'posteriors' is specified; see below).
- **group** - Which group should we give the counts for? See Details.
- **ordering** - If specified, restricts the analysis to a particular ordering on the group.
- **decreasing** - Ordering on posterior likelihoods.
- **number** - How many results should be returned?
- **likelihood** - If given, ignores 'number' and returns all results above a certain likelihood (and FDR, and FWER, if given).
- **FDR** - If given, ignores 'number' and returns all results with an FDR lower than this threshold (and likelihood, and FWER, if given).
- **FWER** - If given, ignores 'number' and returns all results with an FWER lower than this threshold (and likelihood, and FDR, if given).
- **normaliseData** - Should the displayed counts be normalised? See details. Defaults to FALSE.
- **posteriors** - If given, a vector of log-posterior likelihoods to use instead of those in the '@posteriors' slot of the 'cD' object.

Details

The argument 'group' can be specified either as a number, giving the index of an element in the `cD@groups` list, or as a character string identifying an element by name. Partial matching is allowed. If `group = NULL`, then the function looks at the posterior likelihoods that the data have no true differential expression (if calculated).

If a `countData` object is given, the returned dataframe will contain either the raw counts for that object, or (if 'normaliseData = TRUE' the counts normalised by library size.

Value

A dataframe of the top counts associated with some model (group), described by annotation drawn from the '@annotation' slot of the 'cD' object and the raw data from the '@data' slot, together with the posterior likelihoods and false discovery rates.
