Package ‘edgeR’

April 15, 2024

Version 4.0.16
Date 2024-02-18
Title Empirical Analysis of Digital Gene Expression Data in R
Description Differential expression analysis of RNA-seq expression profiles with biological replication. Implements a range of statistical methodology based on the negative binomial distribution, including empirical Bayes estimation, exact tests, generalized linear models and quasi-likelihood tests. As well as RNA-seq, it be applied to differential signal analysis of other types of genomic data that produce read counts, including ChIP-seq, ATAC-seq, Bisulfite-seq, SAGE and CAGE.

## edgeR-package

edgeR is a package for the analysis of digital gene expression data arising from RNA sequencing technologies such as SAGE, CAGE, Tag-seq or RNA-seq, with emphasis on testing for differential expression. It can also be used for other sequencing technologies from which read counts are produced, such as ChIP-seq, Hi-C or CRISPR.

Particular strengths of the package include the ability to estimate biological variation between replicate libraries, and to conduct exact tests of significance which are suitable for small counts. The package is able to make use of even minimal numbers of replicates.

The supplied counts are assumed to be those of genes in a RNA-seq experiment. However, counts can be supplied for any genomic feature of interest, e.g., tags, transcripts, exons, or even arbitrary intervals of the genome.

An extensive User’s Guide is available, and can be opened by typing `edgeRUsersGuide()` at the R prompt. Detailed help pages are also provided for each individual function.

The edgeR package implements original statistical methodology described in the publications below.

### Description

edgeR is a package for the analysis of digital gene expression data arising from RNA sequencing technologies such as SAGE, CAGE, Tag-seq or RNA-seq, with emphasis on testing for differential expression. It can also be used for other sequencing technologies from which read counts are produced, such as ChIP-seq, Hi-C or CRISPR.

Particular strengths of the package include the ability to estimate biological variation between replicate libraries, and to conduct exact tests of significance which are suitable for small counts. The package is able to make use of even minimal numbers of replicates.

The supplied counts are assumed to be those of genes in a RNA-seq experiment. However, counts can be supplied for any genomic feature of interest, e.g., tags, transcripts, exons, or even arbitrary intervals of the genome.

An extensive User’s Guide is available, and can be opened by typing `edgeRUsersGuide()` at the R prompt. Detailed help pages are also provided for each individual function.

The edgeR package implements original statistical methodology described in the publications below.

addPriorCount

Add a prior count

Description

Add a library size-adjusted prior count to each observation.

Usage

addPriorCount(y, lib.size=NULL, offset=NULL, prior.count=1)

Arguments

y a numeric count matrix, with rows corresponding to genes and columns to libraries.
lib.size a numeric vector of library sizes.
offset a numeric vector or matrix of offsets.
prior.count a numeric scalar or vector of prior counts to be added to each gene.

Details

This function adds a positive prior count to each observation, often useful for avoiding zeroes during calculation of log-values. For example, predFC will call this function to calculate shrunken log-fold changes. aveLogCPM and cpm also use the same underlying code to calculate (average) log-counts per million.

The actual value added to the counts for each library is scaled according to the library size. This ensures that the relative contribution of the prior is the same for each library. Otherwise, a fixed prior would have little effect on a large library, but a big effect for a small library.

The library sizes are also modified, with twice the scaled prior being added to the library size for each library. To understand the motivation for this, consider that each observation is, effectively, a proportion of the total count in the library. The addition scheme implemented here represents an empirical logistic transform and ensures that the proportion can never be zero or one.

If offset is supplied, this is used in favour of lib.size where exp(offset) is defined as the vector/matrix of library sizes. If an offset matrix is supplied, this will lead to gene-specific scaling of the prior as described above.

Most use cases of this function will involve supplying a constant value to prior.count for all genes. However, it is also possible to use gene-specific values by supplying a vector of length equal to the number of rows in y.

Value

A list is returned containing y, a matrix of counts with the added priors; and offset, a Compressed-Matrix containing the (log-transformed) modified library sizes.
adjustedProfileLik

Author(s)

Aaron Lun

aveLogCPM, cpm, predFC

Examples

original <- matrix(rnbinom(1000, mu=20, size=10), nrow=200)
head(original)

out <- addPriorCount(original)
head(out$y)
head(out$offset)

adjustedProfileLik

Adjusted Profile Likelihood for the Negative Binomial Dispersion Parameter

Description

Compute adjusted profile log-likelihoods for the dispersion parameters of genewise negative binomial glm.

Usage

adjustedProfileLik(dispersion, y, design, offset, weights=NULL, adjust=TRUE, start=NULL, get.coef=FALSE)

Arguments

dispersion numeric scalar or vector of dispersions.
y numeric matrix of counts.
design numeric matrix giving the design matrix.
offset numeric matrix of same size as y giving offsets for the log-linear models. Can also be a scalar (i.e., a single value) or a vector of length ncol(y), in which case it is expanded out to a matrix.
weights optional numeric matrix giving observation weights.
adjust logical, if TRUE then Cox-Reid adjustment is made to the log-likelihood, if FALSE then the log-likelihood is returned without adjustment.
start numeric matrix of starting values for the GLM coefficients, to be passed to glmFit.
get.coef logical, specifying whether fitted GLM coefficients should be returned.
Details

For each row of data, compute the adjusted profile log-likelihood for the dispersion parameter of the negative binomial glm. The adjusted profile likelihood is described by McCarthy et al (2012) and is based on the method of Cox and Reid (1987).

The adjusted profile likelihood is an approximation to the log-likelihood function, conditional on the estimated values of the coefficients in the NB log-linear models. The conditional likelihood approach is a technique for adjusting the likelihood function to allow for the fact that nuisance parameters have to be estimated in order to evaluate the likelihood. When estimating the dispersion, the nuisance parameters are the coefficients in the log-linear model.

This implementation calls the LAPACK library to perform the Cholesky decomposition during adjustment estimation.

The purpose of start and get.coef is to allow hot-starting for multiple calls to adjustedProfileLik, when only the dispersion is altered. Specifically, the returned GLM coefficients from one call with get.coef=TRUE can be used as the start values for the next call.

The weights argument is interpreted in terms of averages. Each value of y is assumed to be the average of n independent and identically distributed NB counts, where n is given by the weight. This assumption can be generalized to fractional weights.

Value

If get.coef==FALSE, a vector of adjusted profile log-likelihood values is returned containing one element for each row of y.

Otherwise, a list is returned containing apl, the aforementioned vector of adjusted profile likelihoods, and beta, the numeric matrix of fitted GLM coefficients.

glmFit

Examples

```r
y <- matrix(rnbinom(30, mu=10, size=20), 10, 3)
design <- matrix(1, 3, 1)
dispersion <- 0.05
adjustedProfileLik(dispersion, y, design, offset=0)
```
as.data.frame  

Collapse TopTags or Other edgeR Object to a Data Frame

Description

Turn a TopTags object into a data.frame.

Usage

## S3 method for class 'TopTags'
as.data.frame(x, row.names = NULL, ...)

Arguments

x an object of class TopTags, DGEList, DGELM, DGEEexact or DGELRT.
row.names NULL or a character vector giving the row names for the data frame. Missing values are not allowed.
... other arguments are not currently used.

Details

Convert edgeR objects into data.frames. This method returns the table component of a TopTags object. For DGEEexact and DGELRT objects, the genes and table components are combined into a data.frame, similar to what is done by topTags but without sorting or p-value adjustment. For DGEList, the genes and counts components are combined into a data.frame.

Amongst other things, this functionality allows edgeR objects to be written to files using write.table or write.csv.

Value

A data.frame.

Author(s)

Gordon Smyth

See Also

as.data.frame in the base package.
as.matrix

Collapse a DGEList or DGEGLM Object to a Matrix

Description

Coerce a digital gene expression object into a numeric matrix by extracting the count values.

Usage

```r
## S3 method for class 'DGEList'
as.matrix(x,...)
```

Arguments

- `x`: an object of class DGEList or DGEGLM.
- `...`: additional arguments, not used for these methods.

Details

This method extracts the matrix of counts from a DGEList or the matrix of coefficients from a DGEGLM fit.

This involves loss of information, so the original data object is not recoverable.

Value

A numeric matrix.

Author(s)

Gordon Smyth

See Also

as.matrix in the base package or as.matrix in the limma package.
aveLogCPM

Average Log Counts Per Million

Description

Compute average log2 counts-per-million for each row of counts.

Usage

```r
## S3 method for class 'DGEList'
aveLogCPM(y, normalized.lib.sizes=TRUE, prior.count=2, dispersion=NULL, ...)
## S3 method for class 'SummarizedExperiment'
aveLogCPM(y, normalized.lib.sizes=TRUE, prior.count=2,
          dispersion=NULL, ...)
## Default S3 method:
aveLogCPM(y, lib.size=NULL, offset=NULL, prior.count=2, dispersion=NULL,
          weights=NULL, ...)
```

Arguments

- `y`: numeric matrix containing counts. Rows for genes and columns for libraries.
- `normalized.lib.sizes`: logical, use normalized library sizes?
- `prior.count`: numeric scalar or vector of length `nrow(y)`, containing the average value(s) to be added to each count to avoid infinite values on the log-scale.
- `dispersion`: numeric scalar or vector of negative-binomial dispersions. Defaults to 0.05.
- `lib.size`: numeric vector of library sizes. Defaults to `colSums(y)`. Ignored if `offset` is not NULL.
- `offset`: numeric matrix of offsets for the log-linear models.
- `weights`: optional numeric matrix of observation weights.
- `...`: other arguments are not currently used.

Details

This function uses `mglmOneGroup` to compute average counts-per-million (AveCPM) for each row of counts, and returns log2(AveCPM). An average value of `prior.count` is added to the counts before running `mglmOneGroup`. If `prior.count` is a vector, each entry will be added to all counts in the corresponding row of `y`, as described in `addPriorCount`.

This function is similar to

\[ \log_2(\text{rowMeans}(\text{cpm}(y, ...))) \]

but with the refinement that larger library sizes are given more weight in the average. The two versions will agree for large values of the dispersion.
Value

Numeric vector giving log2(AveCPM) for each row of y.

Author(s)

Gordon Smyth

See Also

See cpm for individual logCPM values, rather than genewise averages.

Addition of the prior count is performed using the strategy described in addPriorCount.

The computations for aveLogCPM are done by mglmOneGroup.

Examples

```r
y <- matrix(c(0, 100, 30, 40), 2, 2)
lib.size <- c(1000, 10000)

# With disp large, the function is equivalent to row-wise averages of individual cpms:
aveLogCPM(y, dispersion=1e4)
cpm(y, log=TRUE, prior.count=2)

# With disp=0, the function is equivalent to pooling the counts before dividing by lib.size:
aveLogCPM(y, prior.count=0, dispersion=0)

cpms <- rowSums(y)/sum(lib.size)*1e6
log2(cpms)

# The function works perfectly with prior.count or dispersion vectors:
aveLogCPM(y, prior.count=runif(nrow(y), 1, 5))
aveLogCPM(y, dispersion=runif(nrow(y), 0, 0.2))
```

---

**Description**

Computes p-values for differential abundance for each gene between two digital libraries, conditioning on the total count for each gene. The counts in each group as a proportion of the whole are assumed to follow a binomial distribution.

**Usage**

```r
binomTest(y1, y2, n1=sum(y1), n2=sum(y2), p=n1/(n1+n2))
```
binomTest

Arguments

y1 integer vector giving the count for each gene in the first library. Non-integer
values are rounded to the nearest integer.
y2 integer vector giving the count for each gene in the second library. Of same
length as y1. Non-integer values are rounded to the nearest integer.
n1 total number of counts in the first library, across all genes. Non-integer values
are rounded to the nearest integer. Not required if p is supplied.
n2 total number of counts in the second library, across all genes. Non-integer values
are rounded to the nearest integer. Not required if p is supplied.
p expected proportion of y1 to the total for each gene under the null hypothesis.

Details
This function can be used to compare two libraries from SAGE, RNA-Seq, ChIP-Seq or other
sequencing technologies with respect to technical variation.

An exact two-sided binomial test is computed for each gene. This test is closely related to Fisher’s
exact test for 2x2 contingency tables but, unlike Fisher’s test, it conditions on the total number of
counts for each gene. The null hypothesis is that the expected counts are in the same proportions as
the library sizes, i.e., that the binomial probability for the first library is n1/(n1+n2).

The two-sided rejection region is chosen analogously to Fisher’s test. Specifically, the rejection
region consists of those values with smallest probabilities under the null hypothesis.

When the counts are reasonably large, the binomial test, Fisher’s test and Pearson’s chisquare all
give the same results. When the counts are smaller, the binomial test is usually to be preferred in
this context.

This function replaces the earlier sage.test functions in the statmod and sagenhaft packages. It
produces the same results as binom.test in the stats package, but is much faster.

Value
Numeric vector of p-values.

sage.test (statmod package), binom.test (stats package)
Examples

```r
binomTest(c(0,5,10),c(0,30,50),n1=10000,n2=15000)
# Univariate equivalents:
binom.test(5,5+30,p=10000/(10000+15000))$p.value
binom.test(10,10+50,p=10000/(10000+15000))$p.value
```

---

**camera.DGEGLM**

*Competitive Gene Set Tests for Digital Gene Expression Data*

Description

Test whether a set of genes is highly ranked relative to other genes in terms of differential expression, accounting for inter-gene correlation.

Usage

```r
## S3 method for class 'DGEGLM'
camera(y, index, design = NULL, contrast = ncol(design), weights = NULL,
       use.ranks = FALSE, allow.neg.cor=FALSE, inter.gene.cor=0.01, sort = TRUE, ...)
```

Arguments

- `y`: a DGEGLM object.
- `index`: an index vector or a list of index vectors. Can be any vector such that `y[index,]` selects the rows corresponding to the test set. The list can be made using `ids2indices`.
- `design`: design matrix. Defaults to `y$design`.
- `contrast`: contrast of the linear model coefficients for which the test is required. Can be an integer specifying a column of `design`, or else a numeric vector of same length as the number of columns of `design`.
- `weights`: numeric matrix of observation weights of same size as `y`, or a numeric vector of array weights with length equal to `nrow(y)`, or a numeric vector of gene weights with length equal to `nrow(y)`.
- `use.ranks`: do a rank-based test (TRUE) or a parametric test (FALSE)?
- `allow.neg.cor`: should reduced variance inflation factors be allowed for negative correlations?
- `inter.gene.cor`: numeric, optional preset value for the inter-gene correlation within tested sets. If NA or NULL, then an inter-gene correlation will be estimated for each tested set.
- `sort`: logical, should the results be sorted by p-value?
- `...`: other arguments are not currently used
Details

The camera gene set test was proposed by Wu and Smyth (2012) for microarray data. This function makes the camera test available for digital gene expression data. The negative binomial count data is converted to approximate normal deviates by computing mid-p quantile residuals (Dunn and Smyth, 1996; Routledge, 1994) under the null hypothesis that the contrast is zero. See camera for more description of the test and for a complete list of possible arguments.

Value

A data.frame giving the gene set results, with most significant sets to the top. See camera for details.

```
catchSalmon  

**Process kallisto or Salmon Output**

**Description**

Read transcript counts from kallisto or Salmon output for a series of biological samples and use bootstrap samples to estimate the read-to-transcript ambiguity for each transcript.

**Usage**

```r
catchKallisto(paths, verbose = TRUE)
catchSalmon(paths, verbose = TRUE)
```

**Arguments**

- `paths`  
  character vector giving paths to the directories created by the pseudoaligner (either kallisto or Salmon). Each entry corresponds to one RNA-seq sample.
- `verbose`  
  logical. If TRUE, summary information is shown as each sample is processed.

**Details**

These functions assume that kallisto (Bray et al 2016) or Salmon (Patro et al 2017; Zakeri et al 2017) have been run to obtain estimated transcript counts for one or more RNA samples and that bootstrap samples have also been generated. These functions catch the counts and use the bootstrap samples to estimate an overdispersion parameter for each transcript. The overdispersion represents the variance inflation that occurs from ambiguity in assigning sequence reads to transcripts. Transcripts that overlap other transcripts and have greater quantification uncertainty will have larger overdispersions.

To assess differential transcript expression, the transcript counts can be divided by the overdispersion parameters, after which the scaled counts can be input into standard differential expression pipelines designed for gene-level counts (Baldoni et al 2023). The edgeR quasi pipeline has been found to perform well with the scaled counts (Baldoni et al 2023). The scaled counts behave much like negative binomial counts and show the same mean-variance trends as for gene-level RNA-seq counts.

**Value**

A list containing components

- `counts`  
  matrix of transcript counts
- `annotation`  
  data.frame of transcript information with columns Length, EffectiveLength and Overdispersion.
- `overdispersion.prior`  
  median overdispersion, used to moderate the transcript-wise overdispersion values.
- `resample.type`  
  character vector giving type of resampling ("bootstrap" or "gibbs") for each sample. Only for catchSalmon.
cbind

Author(s)
Gordon Smyth

References

Examples
```r
## Not run:
# Read Salmon output and estimate overdispersion for each transcript
s <- catchSalmon(paths)

# Scale the transcript counts ready for a standard edgeR DE analysis
dge <- DGEList(counts=s$counts/s$annotation$Overdispersion, genes=s$annotation)

## End(Not run)
```

cbind

Combine DGEList Objects

Description
Combine a set of DGEList objects.

Usage
```r
## S3 method for class 'DGEList'
cbind(..., deparse.level=1)
## S3 method for class 'DGEList'
rbind(..., deparse.level=1)
```

Arguments
- `...` DGEList objects.
- `deparse.level` not currently used, see `cbind` in the base package
Generalized Linear Models for Differentially Expressed Genes

Details

cbind combines data objects assuming the same genes in the same order but different samples. rbind combines data objects assuming equivalent samples, i.e., the same RNA targets, but different genes.

For cbind, the matrices of count data from the individual objects are cbinded. The data.frames of samples information, if they exist, are rbinded. The combined data object will preserve any additional components or attributes found in the first object to be combined. For rbind, the matrices of count data are rbinded while the sample information is unchanged.

Value

An DGEList object holding data from all samples and all genes from the individual objects.

Author(s)

Gordon Smyth

cbind in the base package.

Examples

```r
## Not run:
dge <- cbind(dge1,dge2,dge3)
## End(Not run)
```

---

commonCondLogLikDerDelta

*Conditional Log-Likelihoods in Terms of Delta*

Description

Common conditional log-likelihood parameterized in terms of delta (\(\frac{\phi}{\phi+1}\))

Usage

```r
commonCondLogLikDerDelta(y, delta, der = 0)
```

Arguments

- `y`: list with elements comprising the matrices of count data (or pseudocounts) for the different groups
- `delta`: delta (\(\frac{\phi}{\phi+1}\)) parameter of negative binomial
- `der`: derivative, either 0 (the function), 1 (first derivative) or 2 (second derivative)
Details

The common conditional log-likelihood is constructed by summing over all of the individual gene-wise conditional log-likelihoods. The common conditional log-likelihood is taken as a function of the dispersion parameter (phi), and here parameterized in terms of delta (phi / (phi+1)). The value of delta that maximizes the common conditional log-likelihood is converted back to the phi scale, and this value is the estimate of the common dispersion parameter used by all genes.

Value

numeric scalar of function/derivative evaluated at given delta

Author(s)

Davis McCarthy

See Also

estimateCommonDisp is the user-level function for estimating the common dispersion parameter.

Examples

```r
counts<-matrix(rnbinom(20,size=1,mu=10),nrow=5)
d<-DGEList(counts=counts,group=rep(1:2,each=2),lib.size=rep(c(1000:1001),2))
y<-splitIntoGroups(d)
ll1<-commonCondLogLikDerDelta(y,delta=0.5,der=0)
ll2<-commonCondLogLikDerDelta(y,delta=0.5,der=1)
```
der \hspace{1cm} \text{integer specifying derivative required, either 0 (the function), 1 (first derivative) or 2 (second derivative)}

Details

The library sizes must be equalized before running this function. This function carries out the actual mathematical computations for the conditional log-likelihood and its derivatives, calculating the conditional log-likelihood for each gene. Derivatives are with respect to either the size ($r$) or the delta parametrization (delta) of the dispersion.

Value

vector of row-wise derivatives with respect to $r$ or delta

Author(s)

Mark Robinson, Davis McCarthy, Gordon Smyth

Examples

\begin{verbatim}
y <- matrix(rnbinom(10, size=1, mu=10), nrow=5)
condLogLikDerSize(y, r=1, der=1)
condLogLikDerDelta(y, delta=0.5, der=1)
\end{verbatim}

.cpmp \hspace{1cm} \text{Counts per Million or Reads per Kilobase per Million}

Description

Compute counts per million (CPM) or reads per kilobase per million (RPKM).

Usage

\begin{verbatim}
## S3 method for class 'DGEList'
cpm(y, normalized.lib.sizes = TRUE, log = FALSE, prior.count = 2, ...)
## S3 method for class 'SummarizedExperiment'
cpm(y, normalized.lib.sizes = TRUE, log = FALSE, prior.count = 2, ...)
## S3 method for class 'DGEGLM'
cpm(y, log = FALSE, shrunk = TRUE, ...)
## Default S3 method:
cpm(y, lib.size = NULL, offset=NULL, log = FALSE, prior.count = 2, ...)
## S3 method for class 'DGEList'
rpkm(y, gene.length = NULL, normalized.lib.sizes = TRUE, log = FALSE, prior.count = 2, ...)
## S3 method for class 'SummarizedExperiment'
\end{verbatim}
Arguments

- **y**: a matrix-like object containing counts. Can be a numeric matrix, a DGEList object, a SummarizedExperiment object with a "counts" assay, or any object that can be coerced to a matrix by `as.matrix`. For `cpm` and `rpkm`, it can also be a DGEGLM or DGELRT object.
- **normalized.lib.sizes**: logical, use normalized library sizes?
- **lib.size**: library size, defaults to `colSums(y)`. Ignored if `offset` is specified.
- **offset**: numeric matrix of same size as `y`, or a vector of length `ncol(y)`, representing library sizes on the log scale. Can also be a scalar for `cpmByGroup.default` and `rpkmByGroup.default`. If specified, then takes precedence over `lib.size`.
- **log**: logical, if TRUE then log2 values are returned.
- **prior.count**: average count to be added to each observation to avoid taking log of zero. Used only if `log=TRUE`.
- **shrunk**: logical, if TRUE then the usual coefficients from the fitted object will be used, if FALSE then the unshrunk coefficients will be used.
- **gene.length**: vector of length `nrow(y)` giving gene length in bases, or the name of the column `y$genes` containing the gene lengths.
- **group**: factor giving group membership for columns of `y`. Defaults to `y$sample$group` for the DGEList method and to a single level factor for the default method.
- **dispersion**: numeric vector of negative binomial dispersions.
- **weights**: numeric vector or matrix of non-negative quantitative weights. Can be a vector of length equal to the number of libraries, or a matrix of the same size as `y`.
- **...**: other arguments are not used.
Details

CPM or RPKM values are useful descriptive measures for the expression level of a gene. By default, the normalized library sizes are used in the computation for \texttt{DGEList} objects but simple column sums for matrices.

If log-values are computed, then a small count, given by \texttt{prior.count} but scaled to be proportional to the library size, is added to \( y \) to avoid taking the log of zero.

The \texttt{rpkm} methods for \texttt{DGEList}, \texttt{DGEGLM} or \texttt{DGELRT} objects will try to find the gene lengths in a column of \( y \$ \texttt{genes} \) called \texttt{Length} or \texttt{length}. Failing that, it will look for any column name containing "length" in any capitalization.

The \texttt{cpm} and \texttt{rpkm} methods for \texttt{DGEGLM} and \texttt{DGELRT} fitted model objects return fitted CPM or RPKM values. If \texttt{shrink=TRUE}, then the CPM or RPKM values will reflect the \texttt{prior.count} input to the original linear model fit. If \texttt{shrink=FALSE}, then the CPM or RPKM values will be computed with \texttt{prior.count}=0. Note that the latter could result in taking the log of near-zero values if \texttt{log=TRUE}.

c\texttt{pmByGroup} and \texttt{rpkmByGroup} compute group average values on the unlogged scale.

Value

A numeric matrix of CPM or RPKM values, on the log2 scale if \texttt{log=TRUE}. \texttt{cpm} and \texttt{rpkm} produce matrices of the same size as \( y \). If \( y \) was a data object, then observed values are returned. If \( y \) was a fitted model object, then fitted values are returned.

c\texttt{pmByGroup} and \texttt{rpkmByGroup} produce matrices with a column for each level of \texttt{group}.

Note

\texttt{aveLogCPM(y)}, \texttt{rowMeans(cpm(y,log=TRUE))} and \texttt{log2(rowMeans(cpm(y))}) all give slightly different results.

Examples

\begin{verbatim}
y <- matrix(rnbinom(20,size=1,mu=10),5,4)
cpm(y)

d <- DGEList(counts=y, lib.size=1001:1004)
cpm(d)
cpm(d,log=TRUE)

d\$genes <- data.frame(Length=c(1000,2000,500,1500,3000))
rpkm(d)

cpmByGroup(d, group=c(1,1,2,2))
\end{verbatim}
cutWithMinN

```r
rpkmByGroup(d, group=c(1,1,2,2))
```

cutWithMinN | Cut Numeric Vector Into Non-empty Intervals

**Description**

Discretizes a numeric vector. Divides the range of `x` into intervals, so that each interval contains a minimum number of values, and codes the values in `x` according to which interval they fall into.

**Usage**

cutWithMinN(x, intervals=2, min.n=1)

**Arguments**

- `x` numeric vector.
- `intervals` number of intervals required.
- `min.n` minimum number of values in any interval. Must be less than or equal to `length(x)/intervals`.

**Details**

This function strikes a compromise between the base functions `cut`, which by default cuts a vector into equal length intervals, and `quantile`, which is suited to finding equally populated intervals. It finds a partition of the `x` values that is as close as possible to equal length intervals while keeping at least `min.n` values in each interval.

Tied values of `x` are broken by random jittering, so the partition may vary slightly from run to run if there are many tied values.

**Value**

A list with components:

- `group` integer vector of same length as `x` indicating which interval each value belongs to.
- `breaks` numeric vector of length `intervals+1` giving the left and right limits of each interval.

**Author(s)**

Gordon Smyth

**See Also**

cut, quantile.
Examples

```r
x <- c(1,2,3,4,5,6,7,100)
cutWithMinN(x,intervals=3,min.n=1)
```

---

**decideTests**

**Multiple Testing Across Genes and Contrasts**

**Description**

Identify which genes are significantly differentially expressed from an edgeR test object containing p-values and test statistics.

**Usage**

```r
decideTestsDGE(object, adjust.method="BH", p.value=0.05, lfc=0)
# S3 method for class 'DGELRT'
decideTests(object, adjust.method="BH", p.value=0.05, lfc=0, ...)
```

**Arguments**

- `object`: an object of class `DGEExact`, `DGELRT` or `glmQLFTest` from which p-values and log-fold-changes can be extracted.
- `adjust.method`: character string specifying p-value adjustment method. Possible values are "none", "BH", "fdr", "BY" and "holm". See `p.adjust` for details.
- `p.value`: numeric value between 0 and 1 giving the required family-wise error or false discovery rate.
- `lfc`: numeric, minimum absolute log2-fold-change required.
- `...`: other arguments are not used.

**Details**

This function applies a multiple testing procedure and significance level cutoff to the genewise tests contained in an edgeR test object and collates the results in a data.frame table.

The function can apply optionally apply a logFC cutoff and well as a p-value or FDR cutoff (although logFCs cutoff are not recommended, see note below). If the statistical tests are on 1 degree of freedom, then the logFC cutoff is applied to the absolute coefficient or contrast. If the statistical tests are on more than 1 degree of freedom, then the logFC cutoff will be satisfied if any of the coefficients or contrasts that define the test are greater than the cutoff.

`decideTests` and `decideTestsDGE` are equivalent. `decideTestsDGE` is currently retained for backward compatibility but will be removed in a future version of edgeR.
Value

An object of class TestResults. This is essentially a single-column integer matrix with elements -1, 0 or 1 indicating whether each gene is classified as significantly down-regulated, not significant or significant up-regulated for the comparison contained in object. To be considered significant, genes need to have adjusted p-value below p.value and log2-fold-change greater than lfc.

If object contains F-tests or LRTs for multiple contrasts, then the genes are simply classified as significant (1) or not significant. In this case, the log2-fold-change threshold lfc has to be achieved by at least one of the contrasts for a gene to be significant.

Note

Although this function enables users to set p-value and logFC cutoffs simultaneously, this combination criterion is not recommended. logFC cutoffs tend to favor low expressed genes and thereby reduce rather than increase biological significance. Unless the fold changes and p-values are very highly correlated, the addition of a fold change cutoff can also increase the family-wise error rate or false discovery rate above the nominal level. Users wanting to use fold change thresholding should considering using glmTreat instead and leaving lfc at the default value when using decideTests.

Examples

```r
genes <- 100
x1 <- rnorm(6)
x2 <- rnorm(6)
design <- cbind(Intercept=1,x1,x2)
beta <- matrix(0,ngenes,3)
  beta[,1] <- 4
  beta[1:20,2] <- rnorm(20)
mu <- 2^(beta %*% t(design))
y <- matrix(rnbinom(ngenes*6,mu=mu,size=10),ngenes,6)
fit <- glmFit(y,design,dispersion=0.1)
lrt <- glmLRT(fit,coef=2:3)
res <- decideTests(lrt,p.value=0.1)
summary(res)
```
Description

A list-based S4 class for storing results of a differential expression analysis for DGE data.

List Components

For objects of this class, rows correspond to genomic features and columns to statistics associated with the differential expression analysis. The genomic features are called genes, but in reality might correspond to transcripts, tags, exons etc.

Objects of this class contain the following list components:

- **table**: data frame containing columns for the log2-fold-change, logFC, the average log2-counts-per-million, logCPM, and the two-sided p-value PValue.
- **comparison**: vector giving the two experimental groups/conditions being compared.
- **genes**: a data frame containing information about each gene (can be NULL).

Methods

This class inherits directly from class list, so DGEExact objects can be manipulated as if they were ordinary lists. However they can also be treated as if they were matrices for the purposes of subsetting.

The dimensions, row names and column names of a DGEExact object are defined by those of table, see `dim.DGEExact` or `dimnames.DGEExact`.

DGEExact objects can be subbed, see `subsetting`.

DGEExact objects also have a show method so that printing produces a compact summary of their contents.

Other classes defined in edgeR are **DGEList-class, DGEGLM-class, DGELRT-class, TopTags-class**
**DGEGLM-class**

**Description**

A list-based S4 class for storing results of a GLM fit to each gene in a DGE dataset.

**List Components**

For objects of this class, rows correspond to genomic features and columns to coefficients in the linear model. The genomic features are called gene, but in reality might correspond to transcripts, tags, exons, etc.

Objects of this class contain the following list components:

- **coefficients**: matrix containing the coefficients computed from fitting the model defined by the design matrix to each gene in the dataset.
- **df.residual**: vector containing the residual degrees of freedom for the model fit to each gene in the dataset.
- **deviance**: vector giving the deviance from the model fit to each gene.
- **design**: design matrix for the full model from the likelihood ratio test.
- **offset**: scalar, vector or matrix of offset values to be included in the GLMs for each gene.
- **samples**: data frame containing information about the samples comprising the dataset.
- **genes**: data frame containing information about the tags for which we have DGE data (can be NULL if there is no information available).
- **dispersion**: scalar or vector providing the value of the dispersion parameter used in the negative binomial GLM for each gene.
- **lib.size**: vector providing the effective library size for each sample in the dataset.
- **weights**: matrix of weights used in the GLM fitting for each gene.
- **fitted.values**: the fitted (expected) values from the GLM for each gene.
- **AveLogCPM**: numeric vector giving average log2 counts per million for each gene.

**Methods**

This class inherits directly from class `list` so any operation appropriate for lists will work on objects of this class.

The dimensions, row names and column names of a DGEGLM object are defined by those of the dataset, see `dim.DGEGLM` or `dimnames.DGEGLM`.

DGEGLM objects can be subsetted, see `subsetting`.

DGEGLM objects also have a show method so that printing produces a compact summary of their contents.

---

**DGEList**

Create a DGEList object

### Description

Assembles a DGEList object from its components, especially the table counts as a matrix or data.frame.

### Usage

```r
## Default S3 method:
DGEList(counts, lib.size = NULL, norm.factors = NULL, 
samples = NULL, group = NULL, genes = NULL, 
remove.zeros = FALSE, ...)
## S3 method for class 'data.frame'
DGEList(counts, lib.size = NULL, norm.factors = NULL, 
samples = NULL, group = NULL, genes = NULL, 
remove.zeros = FALSE, annotation.columns = NULL, ...)
```

### Arguments

- **counts**: numeric matrix or data.frame containing sequence read counts, with rows corresponding to genes (genomic features) and columns to samples. Negative values or NAs are not allowed.
- **lib.size**: numeric vector of library sizes (sequencing depths) for the samples. Defaults to `colSums(counts)`.
- **norm.factors**: numeric vector of normalization factors that modify the library sizes. Defaults to a vector of ones.
- **samples**: data.frame containing sample information, with a row for each sample. This data.frame will be appended to the `samples` component of the DGEList object.
- **group**: vector or factor giving the experimental group or treatment condition for each sample. Defaults to a single group.
- **genes**: data.frame containing gene annotation.
- **remove.zeros**: logical, whether to remove rows that have 0 total count.
- **annotation.columns**: specify columns of counts that contain gene annotation rather than counts. Can be a vector of column numbers, or a vector of column names, or a logical vector.
- **...**: other arguments are not currently used.
Details

Assembles a DGEList object from its components. The only compulsory argument is the table of counts.

Normally, `counts` is a numeric matrix of counts but a data.frame is also allowed. If the `counts` is a data.frame, then the columns of the data.frame containing gene IDs or other gene annotation can be specified by `annotation.columns`, and the other columns are assumed to contain sequence read counts. If `annotation.columns` is not specified, then the function will check for non-numeric columns of `counts` and will attempt to set the leading columns up to the last non-numeric column as annotation.

Value

A DGEList object.

Author(s)

edgeR team. Originally created by Mark Robinson.

Examples

```r
genases <- 100
nsamples <- 4
Counts <- matrix(rnbinom(genases*nsamples, mu=5, size=10), genases, nsamples)
rownames(Counts) <- 1:genases
colnames(Counts) <- paste0("S", 1:4)
Group <- gl(2, 2)
Genes <- data.frame(Symbol=paste0("Gene", 1:genases))
y <- DGEList(counts=Counts, group=Group, genes=Genes)
dim(y)
colnames(y)
y$samples
show(y)
```

Description

A list-based S4 class for storing read counts and associated information from digital gene expression or sequencing technologies.
List Components

For objects of this class, rows correspond to genomic features and columns to samples. The genomic features are called genes, but in reality might correspond to transcripts, tags, exons etc. Objects of this class contain the following essential list components:

- **counts**: numeric matrix of read counts, one row for each gene and one column for each sample.
- **samples**: data.frame with a row for each sample and columns group, lib.size and norm.factors containing the group labels, library sizes and normalization factors. Other columns can be optionally added to give more detailed sample information.

Optional components include:

- **genes**: data.frame giving annotation information for each gene. Same number of rows as counts.
- **AveLogCPM**: numeric vector giving average log2 counts per million for each gene.
- **common.dispersion**: numeric scalar giving the overall dispersion estimate.
- **trended.dispersion**: numeric vector giving trended dispersion estimates for each gene.
- **tagwise.dispersion**: numeric vector giving tagwise dispersion estimates for each gene (note that ‘tag’ and ‘gene’ are synonymous here).
- **offset**: numeric matrix of same size as counts giving offsets for use in log-linear models.

Methods

This class inherits directly from class list, so DGEList objects can be manipulated as if they were ordinary lists. However they can also be treated as if they were matrices for the purposes of subsetting.

The dimensions, row names and column names of a DGEList object are defined by those of counts, see `dim.DGEList` or `dimnames.DGEList`.

DGEList objects can be subsetted, see `subsetting`.

DGEList objects also have a show method so that printing produces a compact summary of their contents.

Author(s)

edgeR team. First created by Mark Robinson.

DGEList constructs DGEList objects. Other classes defined in edgeR are DGEExact-class, DGEGLM-class, DGELRT-class, TopTags-class
Description

A list-based S4 class for storing results of a GLM-based differential expression analysis for DGE data.

List Components

For objects of this class, rows correspond to genomic features and columns to statistics associated with the differential expression analysis. The genomic features are called genes, but in reality might correspond to transcripts, tags, exons etc.

Objects of this class contain the following list components:

- **table**: data frame containing the log-concentration (i.e. expression level), the log-fold change in expression between the two groups/conditions and the exact p-value for differential expression, for each gene.
- **coefficients.full**: matrix containing the coefficients computed from fitting the full model (fit using glmFit and a given design matrix) to each gene in the dataset.
- **coefficients.null**: matrix containing the coefficients computed from fitting the null model to each gene in the dataset. The null model is the model to which the full model is compared, and is fit using glmFit and dropping selected column(s) (i.e. coefficient(s)) from the design matrix for the full model.
- **design**: design matrix for the full model from the likelihood ratio test.
- **...**: if the argument y to glmLRT (which produces the DGELRT object) was itself a DGLList object, then the DGELRT will contain all of the elements of y, except for the table of counts and the table of pseudocounts.

Methods

This class inherits directly from class list, so DGELRT objects can be manipulated as if they were ordinary lists. However they can also be treated as if they were matrices for the purposes of subsetting.

The dimensions, row names and column names of a DGELRT object are defined by those of table, see dim.DGELRT or dimnames.DGELRT.

DGELRT objects can be subsetted, see subsetting.

DGELRT objects also have a show method so that printing produces a compact summary of their contents.

---

diffSpliceDGE  
*Test for Differential Exon Usage*

Description

Given a negative binomial generalized log-linear model fit at the exon level, test for differential exon usage between experimental conditions.

Usage

diffSpliceDGE(glmfit, coef=ncol(glmfit$design), contrast=NULL, geneid, exonid=NULL, prior.count=0.125, verbose=TRUE)

Arguments

- `glmfit`: an DGEGLM fitted model object produced by `glmFit` or `glmQLFit`. Rows should correspond to exons.
- `coef`: integer indicating which coefficient of the generalized linear model is to be tested for differential exon usage. Defaults to the last coefficient.
- `contrast`: numeric vector specifying the contrast of the linear model coefficients to be tested for differential exon usage. Length must equal to the number of columns of `design`. If specified, then takes precedence over `coef`.
- `geneid`: gene identifiers. Either a vector of length `nrow(glmfit)` or the name of the column of `glmfit$genes` containing the gene identifiers. Rows with the same ID are assumed to belong to the same gene.
- `exonid`: exon identifiers. Either a vector of length `nrow(glmfit)` or the name of the column of `glmfit$genes` containing the exon identifiers.
- `prior.count`: average prior count to be added to observation to shrink the estimated log-fold-changes towards zero.
- `verbose`: logical, if `TRUE` some diagnostic information about the number of genes and exons is output.

Details

This function tests for differential exon usage for each gene for a given coefficient of the generalized linear model.

Testing for differential exon usage is equivalent to testing whether the exons in each gene have the same log-fold-changes as the other exons in the same gene. At exon-level, the log-fold-change of each exon is compared to the log-fold-change of the entire gene which contains that exon. At gene-level, two different tests are provided. One is converting exon-level p-values to gene-level p-values by the Simes method. The other is using exon-level test statistics to conduct gene-level tests.
**Value**

diffSpliceDGE produces an object of class DGELRT containing the component design from glmfit plus the following new components:

- `comparison`: character string describing the coefficient being tested.
- `coefficients`: numeric vector of coefficients on the natural log scale. Each coefficient is the difference between the log-fold-change for that exon versus the log-fold-change for the entire gene which contains that exon.
- `genes`: data.frame of exon annotation.
- `genecolname`: character string giving the name of the column of genes containing gene IDs.
- `exoncolname`: character string giving the name of the column of genes containing exon IDs.
- `exon.p.value`: numeric vector of p-values for exons.
- `exon.df.test`: numeric vector of testing degrees of freedom for exons.
- `exon.LR`: numeric vector of LR-statistics for exons.
- `gene.df.test`: numeric vector of testing degrees of freedom for genes.
- `gene.df.prior`: numeric vector of prior degrees of freedom for genes.

Some components of the output depend on whether glmfit is produced by glmFit or glmQLFit. If glmfit is produced by glmFit, then the following components are returned in the output object:

- `exon.LR`: numeric vector of LR-statistics for exons.

If glmfit is produced by glmQLFit, then the following components are returned in the output object:

- `gene.df.prior`: numeric vector of prior degrees of freedom for genes.

The information and testing results for both exons and genes are sorted by geneid and by exonid within gene.

**Author(s)**

Yunshun Chen and Gordon Smyth
Examples

# Gene exon annotation
Gene <- paste("Gene", 1:100, sep="")
Gene <- rep(Gene, each=10)
Exon <- paste("Ex", 1:10, sep="")
Gene.Exon <- paste(Gene, Exon, sep=".")
genes <- data.frame(GeneID=Gene, Gene.Exon=Gene.Exon)

plotSpliceDGE(ds)

---

`dim`  

Retrieve the Dimensions of a `DGEList`, `DGEEexact`, `DGEGLM`, `DGELRT` or `TopTags` Object

Description

Retrieve the number of rows (genes) and columns (libraries) for an `DGEList`, `DGEEexact` or `TopTags` Object.

Usage

```r
## S3 method for class 'DGEList'
dim(x)
```

Arguments

- `x` an object of class `DGEList`, `DGEEexact`, `TopTags`, `DGEGLM` or `DGELRT`

Details

Digital gene expression data objects share many analogies with ordinary matrices in which the rows correspond to genes and the columns to arrays. These methods allow one to extract the size of microarray data objects in the same way that one would do for ordinary matrices. A consequence is that row and column commands `nrow(x)`, `ncol(x)` and so on also work.
Retrieve the Dimension Names of a DGE Object

**Description**

Retrieve the dimension names of a digital gene expression data object.

**Usage**

```r
## S3 method for class 'DGEList'
dimnames(x)
## S3 replacement method for class 'DGEList'
dimnames(x) <- value
```

**Arguments**

- `x` an object of class DGEList, DGEExact, DGEGLM, DGLRT or TopTags
- `value` a possible value for `dimnames(x)`, see `dimnames`

**Details**

The dimension names of a DGE data object are the same as those of the most important component of that object.

Setting dimension names is currently only permitted for DGEList or DGEGLM objects.

A consequence of these methods is that `rownames`, `colnames`, `rownames<-` and `colnames<-` will also work as expected on any of the above object classes.
Value

Either NULL or a list of length 2. If a list, its components are either NULL or a character vector the length of the appropriate dimension of \( x \).

dispBinTrend

Details

Estimate a dispersion parameter for each of many negative binomial generalized linear models by computing the common dispersion for genes sorted into bins based on overall AveLogCPM. A regression natural cubic splines or a linear loess curve is used to smooth the trend and extrapolate a value to each gene.

If there are fewer than \texttt{min.n} rows of \texttt{y} with at least one positive count, then one bin is used. The number of bins is limited to 1000.

Value

list with the following components:

\begin{itemize}
  \item \texttt{AveLogCPM} numeric vector containing the overall AveLogCPM for each gene
  \item \texttt{dispersion} numeric vector giving the trended dispersion estimate for each gene
  \item \texttt{bin.AveLogCPM} numeric vector of length equal to \texttt{nbins} giving the average (mean) AveLogCPM for each bin
  \item \texttt{bin.dispersion} numeric vector of length equal to \texttt{nbins} giving the estimated common dispersion for each bin
\end{itemize}

Author(s)

Davis McCarthy and Gordon Smyth

\end{verbatim}
dispCoxReid

Estimate Common Dispersion for Negative Binomial GLMs

Description

Estimate a common dispersion parameter across multiple negative binomial generalized linear models.

Usage

dispCoxReid(y, design=NULL, offset=NULL, weights=NULL, AveLogCPM=NULL, interval=c(0,4),
  tol=1e-5, min.row.sum=5, subset=10000)
dispDeviance(y, design=NULL, offset=NULL, interval=c(0,4), tol=1e-5, min.row.sum=5,
  subset=10000, AveLogCPM=NULL, robust=FALSE, trace=FALSE)
dispPearson(y, design=NULL, offset=NULL, min.row.sum=5, subset=10000,
  AveLogCPM=NULL, tol=1e-6, trace=FALSE, initial.dispersion=0.1)

Arguments

y numeric matrix of counts. A glm is fitted to each row.
design numeric design matrix, as for glmFit.
offset numeric vector or matrix of offsets for the log-linear models, as for glmFit. Defaults to log(colSums(y)).
weights optional numeric matrix giving observation weights
AveLogCPM numeric vector giving average log2 counts per million.
interval numeric vector of length 2 giving minimum and maximum allowable values for the dispersion, passed to optimize.
tol the desired accuracy, see optimize or uniroot.
min.row.sum integer. Only rows with at least this number of counts are used.
subset integer, number of rows to use in the calculation. Rows used are chosen evenly spaced by AveLogCPM.
trace logical, should iteration information be output?
robust logical, should a robust estimator be used?
initial.dispersion starting value for the dispersion

Details

These are low-level (non-object-orientated) functions called by estimateGLMCommonDisp. dispCoxReid maximizes the Cox-Reid adjusted profile likelihood (Cox and Reid, 1987). dispPearson sets the average Pearson goodness of fit statistics to its (asymptotic) expected value. This is also known as the pseudo-likelihood estimator. dispDeviance sets the average residual deviance statistic to its (asymptotic) expected values. This is also known as the quasi-likelihood estimator.
Robinson and Smyth (2008) and McCarthy et al (2011) showed that the Pearson (pseudo-likelihood) estimator typically under-estimates the true dispersion. It can be seriously biased when the number of libraries (\(\text{ncol}(y)\)) is small. On the other hand, the deviance (quasi-likelihood) estimator typically over-estimates the true dispersion when the number of libraries is small. Robinson and Smyth (2008) and McCarthy et al (2011) showed the Cox-Reid estimator to be the least biased of the three options.

dispCoxReid uses optimize to maximize the adjusted profile likelihood. dispDeviance uses uniroot to solve the estimating equation. The robust options use an order statistic instead the mean statistic, and have the effect that a minority of genes with very large (outlier) dispersions should have limited influence on the estimated value. dispPearson uses a globally convergent Newton iteration.

Value

Numeric vector of length one giving the estimated common dispersion.

Author(s)

Gordon Smyth

\end{align*}
\]
dispCoxReidInterpolateTagwise

Description

Estimate genewise dispersion parameters across multiple negative binomial generalized linear models using weighted Cox-Reid Adjusted Profile-likelihood and cubic spline interpolation over a genewise grid.

Usage

```r
dispCoxReidInterpolateTagwise(y, design, offset=NULL, dispersion, trend=TRUE,
    AveLogCPM=NULL, min.row.sum=5, prior.df=10,
    span=0.3, grid.npts=11, grid.range=c(-6,6),
    weights=NULL)
```

Arguments

- `y`: numeric matrix of counts
- `design`: numeric matrix giving the design matrix for the GLM that is to be fit.
- `offset`: numeric scalar, vector or matrix giving the offset (in addition to the log of the effective library size) that is to be included in the NB GLM for the genes. If a scalar, then this value will be used as an offset for all genes and libraries. If a vector, it should be have length equal to the number of libraries, and the same vector of offsets will be used for each gene. If a matrix, then each library for each gene can have a unique offset, if desired. In `adjustedProfileLik` the offset must be a matrix with the same dimension as the table of counts.
- `dispersion`: numeric scalar or vector giving the dispersion(s) towards which the genewise dispersion parameters are shrunk.
- `trend`: logical, whether abundance-dispersion trend is used for smoothing.
- `AveLogCPM`: numeric vector giving average log2 counts per million for each gene.
- `min.row.sum`: numeric scalar giving a value for the filtering out of low abundance genes. Only genes with total sum of counts above this value are used. Low abundance genes can adversely affect the estimation of the common dispersion, so this argument allows the user to select an appropriate filter threshold for the gene abundance.
- `prior.df`: numeric scalar, prior degsmoothing parameter that indicates the weight to give to the common likelihood compared to the individual gene’s likelihood; default `getPriorN(object)` gives a value for `prior.n` that is equivalent to giving the common likelihood 20 prior degrees of freedom in the estimation of the genewise dispersion.
- `span`: numeric parameter between 0 and 1 specifying proportion of data to be used in the local regression moving window. Larger numbers give smoother fits.
grid.npts numeric scalar, the number of points at which to place knots for the spline-based estimation of the genewise dispersion estimates.

grid.range numeric vector of length 2, giving relative range, in terms of log2(dispersion), on either side of trendline for each gene for spline grid points.

weights optional numeric matrix giving observation weights

Details

In the edgeR context, dispCoxReidInterpolateTagwise is a low-level function called by estimateGLMTagwiseDisp. dispCoxReidInterpolateTagwise calls the function maximizeInterpolant to fit cubic spline interpolation over a genewise grid.

Note that the terms ‘tag’ and ‘gene’ are synonymous here. The function is only named ‘Tagwise’ for historical reasons.

Value

dispCoxReidInterpolateTagwise produces a vector of genewise dispersions having the same length as the number of genes in the count data.

y <- matrix(rnbinom(1000, mu=10, size=2), ncol=4)
design <- matrix(1, 4, 1)
dispersion <- 0.5
d <- dispCoxReidInterpolateTagwise(y, design, dispersion=dispersion)
d```

dispCoxReidSplineTrend

Estimate Dispersion Trend for Negative Binomial GLMs

Description

Estimate trended dispersion parameters across multiple negative binomial generalized linear models using Cox-Reid adjusted profile likelihood.

Usage

dispCoxReidSplineTrend(y, design, offset=NULL, df = 5, subset=10000, AveLogCPM=NULL,
method.optim="Nelder-Mead", trace=0)
dispCoxReidPowerTrend(y, design, offset=NULL, subset=10000, AveLogCPM=NULL,
method.optim="Nelder-Mead", trace=0)

Arguments

y numeric matrix of counts
design numeric matrix giving the design matrix for the GLM that is to be fit.
offset numeric scalar, vector or matrix giving the offset (in addition to the log of the effective library size) that is to be included in the NB GLM for the genes. If a scalar, then this value will be used as an offset for all genes and libraries. If a vector, it should be have length equal to the number of libraries, and the same vector of offsets will be used for each gene. If a matrix, then each library for each gene can have a unique offset, if desired. In adjustedProfileLik the offset must be a matrix with the same dimension as the table of counts.
df integer giving the degrees of freedom of the spline function, see ns in the splines package.
subset integer, number of rows to use in the calculation. Rows used are chosen evenly spaced by AveLogCPM using cutWithMinN.
AveLogCPM numeric vector giving average log2 counts per million for each gene.
method.optim the method to be used in optim. See optim for more detail.
trace logical, should iteration information be output?

Details

In the edgeR context, these are low-level functions called by estimateGLMTrendedDisp.
dispCoxReidSplineTrend and dispCoxReidPowerTrend fit abundance trends to the genewise dispersions. dispCoxReidSplineTrend fits a regression spline whereas dispCoxReidPowerTrend fits a log-linear trend of the form a*exp(abundance)^b+c. In either case, optim is used to maximize the adjusted profile likelihood (Cox and Reid, 1987).
**dropEmptyLevels**

**Value**
List containing numeric vectors dispersion and abundance containing the estimated dispersion and abundance for each gene. The vectors are of the same length as nrow(y).

**Author(s)**
Yunshun Chen, Davis McCarthy, Gordon Smyth

**References**

**See Also**
estimateGLMTrendedDisp

**Examples**
design <- matrix(1,4,1)
y <- matrix(rnbinom(400,mu=100,size=5),100,4)

d2 <- dispCoxReidPowerTrend(y, design)
with(d2,plot(AveLogCPM,sqrt(dispersion)))

dropEmptyLevels

---

**dropEmptyLevels**

*Drop Levels of a Factor that Never Occur*

**Description**
Reform a factor so that only necessary levels are kept.

**Usage**
dropEmptyLevels(x)

**Arguments**

- **x**
  
  A factor or a vector to be converted to a factor.

**Details**
In general, the levels of a factor, levels(x), may include values that never actually occur. This function drops any levels of that do not occur.

If x is not a factor, then the function returns factor(x). If x is a factor, then the function returns the same value as factor(x) or x[, drop=TRUE] but somewhat more efficiently.
Value

A factor with the same values as x but with a possibly reduced set of levels.

Author(s)

Gordon Smyth

See Also

factor.

Examples

```r
x <- factor(c("a","b"), levels=c("c","b","a"))
x
dropEmptyLevels(x)
```

Description

Finds the location of the edgeR User’s Guide and optionally opens it.

Usage

```r
edgeRUsersGuide(view=TRUE)
```

Arguments

- `view` logical, should the document be opened using the default PDF document reader?

Details

The function `vignette("edgeR")` will find the short edgeR Vignette which describes how to obtain the edgeR User’s Guide. The User’s Guide is not itself a true vignette because it is not automatically generated using Sweave during the package build process. This means that it cannot be found using vignette, hence the need for this special function.

If the operating system is other than Windows, then the PDF viewer used is that given by `Sys.getenv("R_PDFVIEWER")`. The PDF viewer can be changed using `Sys.putenv(R_PDFVIEWER=).`

Value

Character string giving the file location. If `view=TRUE`, the PDF document reader is started and the User’s Guide is opened, as a side effect.
equalizeLibSizes

Author(s)
Gordon Smyth

system

Examples

# To get the location:
edgeRUsersGuide(view=FALSE)
# To open in pdf viewer:
## Not run: edgeRUsersGuide()

#### equalizeLibSizes

**Equalize Library Sizes by Quantile-to-Quantile Normalization**

**Description**

Adjusts counts so that the effective library sizes are equal, preserving fold-changes between groups and preserving biological variability within each group.

**Usage**

```
## S3 method for class 'DGEList'
equalizeLibSizes(y, dispersion=NULL, ...)
## Default S3 method:
equalizeLibSizes(y, group=NULL, dispersion=NULL,
                 lib.size=NULL, ...)
```

**Arguments**

- `y` matrix of counts or a DGEList object.
- `dispersion` numeric scalar or vector of dispersion parameters. By default, is extracted from `y` or, if `y` contains no dispersion information, is set to `0.05`.
- `group` vector or factor giving the experimental group/condition for each library.
- `lib.size` numeric vector giving the total count (sequence depth) for each library.
- `...` other arguments that are not currently used.

**Details**

Thus function implements the quantile-quantile normalization method of Robinson and Smyth (2008). It computes normalized counts, or pseudo-counts, used by `exactTest` and `estimateCommonDisp`. The output pseudo-counts are the counts that would have theoretically arisen had the effective library sizes been equal for all samples. The pseudo-counts are computed in such as way as to
preserve fold-change differences between the groups defined by \texttt{samples\$group} as well as biological variability within each group. Consequently, the results will depend on how the groups are defined.

Note that the column sums of the \texttt{pseudo.counts} matrix will not generally be equal, because the effective library sizes are not necessarily the same as actual library sizes and because the normalized pseudo counts are not equal to expected counts.

Value

\texttt{equalizeLibSizes.DGEList} returns a \texttt{DGEList} object with the following new components:

- \texttt{pseudo.counts} numeric matrix of normalized pseudo-counts
- \texttt{pseudo.lib.size} normalized library size

\texttt{equalizeLibSizes.default} returns a list with components \texttt{pseudo.counts} and \texttt{pseudo.lib.size}.

Note

This function is intended mainly for internal edgeR use. It is not normally called directly by users.

Author(s)

Mark Robinson, Davis McCarthy, Gordon Smyth

References

See Also

- \texttt{q2qnbinom}

Examples

```r
gen <- 1000
nlibs <- 2
counts <- matrix(0,ngenes,nlibs)
colnames(counts) <- c("Sample1","Sample2")
counts[,1] <- rpois(ngenes,lambda=10)
counts[,2] <- rpois(ngenes,lambda=20)
summary(counts)
y <- DGEList(counts=counts)
out <- equalizeLibSizes(y)
summary(out$pseudo.counts)
```
**estimateCommonDisp**

Estimate Common Negative Binomial Dispersion by Conditional Maximum Likelihood

**Description**

Maximizes the negative binomial conditional common likelihood to estimate a common dispersion value across all genes.

**Usage**

```r
## S3 method for class 'DGEList'
estimateCommonDisp(y, tol=1e-06, rowsum.filter=5, verbose=FALSE, ...)
## Default S3 method:
estimateCommonDisp(y, group=NULL, lib.size=NULL, tol=1e-06, rowsum.filter=5, verbose=FALSE, ...)
```

**Arguments**

- `y`: matrix of counts or a DGEList object.
- `tol`: the desired accuracy, passed to `optimize`.
- `rowsum.filter`: genes with total count (across all samples) below this value will be filtered out before estimating the dispersion.
- `verbose`: logical, if TRUE then the estimated dispersion and BCV will be printed to standard output.
- `group`: vector or factor giving the experimental group/condition for each library.
- `lib.size`: numeric vector giving the total count (sequence depth) for each library.
- `...`: other arguments that are not currently used.

**Details**

Implements the conditional maximum likelihood (CML) method proposed by Robinson and Smyth (2008) for estimating a common dispersion parameter. This method proves to be accurate and nearly unbiased even for small counts and small numbers of replicates.

The CML method involves computing a matrix of quantile-quantile normalized counts, called pseudo-counts. The pseudo-counts are adjusted in such a way that the library sizes are equal for all samples, while preserving differences between groups and variability within each group. The pseudo-counts are included in the output of the function, but are intended mainly for internal edgeR use.

**Value**

`estimateCommonDisp.DGEList` adds the following components to the input DGEList object:

- `common.dispersion`: estimate of the common dispersion.
estimateDisp

pseudo.counts   numeric matrix of pseudo-counts.

pseudo.lib.size 
the common library size to which the pseudo-counts have been adjusted.

AveLogCPM      numeric vector giving log2(AveCPM) for each row of y.

estimateCommonDisp.default returns a numeric scalar of the common dispersion estimate.

dge <- estimateCommonDisp(dge, verbose=TRUE)

estimateDisp Estimate Common, Trended and Tagwise Negative Binomial dispersions by weighted likelihood empirical Bayes

Description
Maximizes the negative binomial likelihood to give the estimate of the common, trended and tagwise dispersions across all tags.

Usage
## S3 method for class 'DGEList'
estimateDisp(y, design=NULL, prior.df=NULL, trend.method="locfit", tagwise=TRUE, 
span=NULL, min.row.sum=5, grid.length=21, grid.range=c(-10,10), 
robust=FALSE, winsor.tail.p=c(0.05,0.1), tol=1e-06, ...) 

## S3 method for class 'SummarizedExperiment'
estimateDisp(y, design=NULL, prior.df=NULL, trend.method="locfit", tagwise=TRUE, 
span=NULL, min.row.sum=5, grid.length=21, grid.range=c(-10,10), 
robust=FALSE, winsor.tail.p=c(0.05,0.1), tol=1e-06, ...) 

## Default S3 method:

# S3 method for class 'DGEList'
estimateDisp(y, design=NULL, prior.df=NULL, trend.method="locfit", tagwise=TRUE, 
span=NULL, min.row.sum=5, grid.length=21, grid.range=c(-10,10), 
robust=FALSE, winsor.tail.p=c(0.05,0.1), tol=1e-06, ...) 

# S3 method for class 'SummarizedExperiment'
estimateDisp(y, design=NULL, prior.df=NULL, trend.method="locfit", tagwise=TRUE, 
span=NULL, min.row.sum=5, grid.length=21, grid.range=c(-10,10), 
robust=FALSE, winsor.tail.p=c(0.05,0.1), tol=1e-06, ...) 

# Default S3 method:
estimateDisp(y, design=NULL, group=NULL, lib.size=NULL, offset=NULL, 
  prior.df=NULL, trend.method="locfit", tagwise=TRUE, span=NULL, 
  min.row.sum=5, grid.length=21, grid.range=c(-10,10), 
  robust=FALSE, winsor.tail.p=c(0.05,0.1), tol=1e-06, weights=NULL, ...)

Arguments

y matrix of counts, or a DGEList object, or a SummarizedExperiment object.

design numeric design matrix. Defaults to model.matrix(~group) if group is speci-

fied and otherwise to a single column of ones.

prior.df prior degrees of freedom. It is used in calculating prior.n.

trend.method method for estimating dispersion trend. Possible values are "locfit" (default),

"none", "movingave", "loess" and "locfit.mixed", which uses a polyno-

mial of degree 1 for lowly expressed genes.

tagwise logical, should the tagwise dispersions be estimated?

span width of the smoothing window, as a proportion of the data set.

min.row.sum numeric scalar giving a value for the filtering out of low abundance tags. Only
tags with total sum of counts above this value are used. Low abundance tags
can adversely affect the dispersion estimation, so this argument allows the user
to select an appropriate filter threshold for the tag abundance.

grid.length the number of points on which the interpolation is applied for each tag.

grid.range the range of the grid points around the trend on a log2 scale.

robust logical, should the estimation of prior.df be robustified against hypervariable
genes?

winsor.tail.p numeric vector of length 1 or 2, giving left and right tail proportions of the
deviances to Winsorize when estimating prior.df.

tol the desired accuracy, passed to optimize

group vector or factor giving the experimental group/condition for each library. De-

faults to a vector of ones with length equal to the number of libraries.

lib.size numeric vector giving the total count (sequence depth) for each library.

offset offset matrix for the log-linear model, as for glmFit. Defaults to the log-
effective library sizes.

weights optional numeric matrix giving observation weights

... other arguments that are not currently used.

Details

This function calculates a matrix of likelihoods for each tag at a set of dispersion grid points, and
then applies weighted likelihood empirical Bayes method to obtain posterior dispersion estimates. If
there is no design matrix, it calculates the quantile conditional likelihood for each tag and then maxi-
mizes it. In this case, it is similar to the function estimateCommonDisp and estimateTagwiseDisp.
If a design matrix is given, it calculates the adjusted profile log-likelihood for each tag and then maxi-
mizes it. In this case, it is similar to the functions estimateGLMCommonDisp, estimateGLMTrendedDisp
and estimateGLMTagwiseDisp.

Note that the terms ‘tag’ and ‘gene’ are synonymous here.
Value

estimateDisp.DGEList adds the following components to the input DGEList object:

design the design matrix.
common.dispersion estimate of the common dispersion.
trended.dispersion estimates of the trended dispersions.
tagwise.dispersion tagwise estimates of the dispersion parameter if tagwise=TRUE.
AveLogCPM numeric vector giving log2(AveCPM) for each row of y.
trend.method method for estimating dispersion trend as given in the input.
prior.df prior degrees of freedom. If robust=TRUE then prior.df is a vector with smaller values assigned to hypervariable outlier genes.
prior.n estimate of the prior weight, i.e. the smoothing parameter that indicates the weight to put on the common likelihood compared to the individual tag’s likelihood.
span width of the smoothing window used in estimating dispersions.

estimateDisp.SummarizedExperiment converts the input SummarizedExperiment object into a DGEList object, and then calls estimateDisp.DGEList. The output is a DGEList object.

estimateDisp.default returns a list containing common.dispersion, trended.dispersion, tagwise.dispersion (if tagwise=TRUE), span, prior.df and prior.n.

Note

The estimateDisp function doesn’t give exactly the same estimates as the traditional calling sequences.

estimateCommonDisp, estimateTagwiseDisp, estimateGLMCommonDisp, estimateGLMTrendedDisp, estimateGLMTagwiseDisp
estimateExonGenewiseDisp

Estimate Genewise Dispersions from Exon-Level Count Data

Description
Estimate a dispersion value for each gene from exon-level count data by collapsing exons into the genes to which they belong.

Usage
estimateExonGenewiseDisp(y, geneID, group=NULL)

Arguments
- `y`: either a matrix of exon-level counts or a DGEList object with (at least) elements `counts` (table of counts summarized at the exon level) and `samples` (data frame containing information about experimental group, library size and normalization factor for the library size). Each row of `y` should represent one exon.
- `geneID`: vector of length equal to the number of rows of `y`, which provides the gene identifier for each exon in `y`. These identifiers are used to group the relevant exons into genes for the gene-level analysis of splice variation.
- `group`: factor supplying the experimental group/condition to which each sample (column of `y`) belongs. If `NULL` (default) the function will try to extract it from `y`, which only works if `y` is a DGEList object.

Details
This function can be used to compute genewise dispersion estimates (for an experiment with a one-way, or multiple group, layout) from exon-level count data. `estimateCommonDisp` and `estimateTagwiseDisp` are used to do the computation and estimation, and the default arguments for those functions are used.

Value
`estimateExonGenewiseDisp` returns a vector of genewise dispersion estimates, one for each unique geneID.

estimateExonGenewiseDisp(d, genes)

estimateGLMCommonDisp  Estimate Common Dispersion for Negative Binomial GLMs

Description

Estimates a common negative binomial dispersion parameter for a DGE dataset with a general experimental design.

Usage

## S3 method for class 'DGEList'
estimateGLMCommonDisp(y, design=NULL, method="CoxReid",
                      subset=10000, verbose=FALSE, ...)

## Default S3 method:
estimateGLMCommonDisp(y, design=NULL, offset=NULL,
                      method="CoxReid", subset=10000, AveLogCPM=NULL,
                      verbose=FALSE, weights=NULL,...)

Arguments

y object containing read counts, as for glmFit.
design numeric design matrix, as for glmFit.
offset numeric vector or matrix of offsets for the log-linear models, as for glmFit.
method method for estimating the dispersion. Possible values are "CoxReid", "Pearson" or "deviance".
subset maximum number of rows of y to use in the calculation. Rows used are chosen evenly spaced by AveLogCPM using systematicSubset.
AveLogCPM numeric vector giving average log2 counts per million for each gene.
verbose logical, if TRUE estimated dispersion and BCV will be printed to standard output.
weights optional numeric matrix giving observation weights
... other arguments are passed to lower-level functions. See dispCoxReid, dispPearson and dispDeviance for details.
**Details**

This function calls `dispCoxReid`, `dispPearson` or `dispDeviance` depending on the method specified. See `dispCoxReid` for details of the three methods and a discussion of their relative performance.

**Value**

The default method returns a numeric vector of length 1 containing the estimated common dispersion.

The DGEList method returns the same DGEList y as input but with `common.dispersion` as an added component. The output object will also contain a component `AveLogCPM` if it was not already present in y.

**Author(s)**

Gordon Smyth, Davis McCarthy, Yunshun Chen

**References**

**See Also**

`dispCoxReid, dispPearson, dispDeviance`

`estimateGLMTrendedDisp` for trended dispersions or `estimateGLMTagwiseDisp` for genewise dispersions in the context of a generalized linear model.

`estimateCommonDisp` for the common dispersion or `estimateTagwiseDisp` for genewise dispersions in the context of a multiple group experiment (one-way layout).

**Examples**

```r
# True dispersion is 1/size=0.1
y <- matrix(rnbinom(1000,mu=10,size=10),ncol=4)
d <- DGEList(counts=y,group=c(1,1,2,2))
design <- model.matrix(~group, data=d$samples)
d1 <- estimateGLMCommonDisp(d, design, verbose=TRUE)

# Compare with classic CML estimator:
d2 <- estimateCommonDisp(d, verbose=TRUE)

# See example(glmFit) for a different example
```
**Description**

Compute a robust estimate of the negative binomial dispersion parameter for each gene, with expression levels specified by a log-linear model, using observation weights. These observation weights will be stored and used later for estimating regression parameters.

**Usage**

```r
estimateGLMRobustDisp(y, design = NULL, prior.df = 10, update.trend = TRUE, trend.method = "bin.loess", maxit = 6, k = 1.345, residual.type = "pearson", verbose = FALSE, record = FALSE)
```

**Arguments**

- **y**: a DGEList object.
- **design**: numeric design matrix, as for `glmFit`.
- **prior.df**: prior degrees of freedom.
- **update.trend**: logical. Should the trended dispersion be re-estimated at each iteration?
- **trend.method**: method (low-level function) used to estimated the trended dispersions. `estimateGLMTrendedDisp`.
- **maxit**: maximum number of iterations for weighted `estimateGLMTagwiseDisp`.
- **k**: the tuning constant for Huber estimator. If the absolute value of residual (r) is less than k, its observation weight is 1, otherwise k/abs(r).
- **residual.type**: type of residual (r) used for estimation observation weight.
- **verbose**: logical. Should verbose comments be printed?
- **record**: logical. Should information for each iteration be recorded (and returned as a list)?

**Details**

Moderation of dispersion estimates towards a trend can be sensitive to outliers, resulting in an increase in false positives. That is, since the dispersion estimates are moderated downwards toward the trend and because the regression parameter estimates may be affected by the outliers, some genes are incorrectly deemed to be significantly differentially expressed. This function uses an iterative procedure where weights are calculated from residuals and estimates are made after re-weighting.

The robustly computed genewise estimates are reported in the `tagwise.dispersion` vector of the returned DGEList. The terms ‘tag’ and ‘gene’ are synonymous in this context.

Note: it is not necessary to first calculate the common, trended and genewise dispersion estimates. If these are not available, the function will first calculate this (in an unweighted) fashion.
**Value**

`estimateGLMRobustDisp` produces a `DGEList` object, which contains the (robust) gene-wise dispersion parameter estimate for each gene for the negative binomial model that maximizes the weighted Cox-Reid adjusted profile likelihood, as well as the observation weights. The observation weights are calculated using residuals and the Huber function.

Note that when `record=TRUE`, a simple list of `DGEList` objects is returned, one for each iteration (this is for debugging or tracking purposes).

This function calls `estimateGLMTrendedDisp` and `estimateGLMTagwiseDisp`.

**Examples**

```r
y <- matrix(rnbinom(100*6,mu=10,size=1/0.1),ncol=6)
d <- DGEList(counts=y, group=c(1,1,1,2,2,2), lib.size=c(1000:1005))
d <- normLibSizes(d) # Define the design matrix for the full model
d <- estimateGLMRobustDisp(d, design)
summary(d$tagwise.dispersion)
```

---

**estimateGLMTagwiseDisp**

*Empirical Bayes Tagwise Dispersions for Negative Binomial GLMs*

**Description**

Compute an empirical Bayes estimate of the negative binomial dispersion parameter for each tag, with expression levels specified by a log-linear model.

**Usage**

```r
## S3 method for class 'DGEList'
estimateGLMTagwiseDisp(y, design=NULL, prior.df=10, trend=!is.null(y$trended.dispersion), span=NULL, ...)

## Default S3 method:
estimateGLMTagwiseDisp(y, design=NULL, offset=NULL, dispersion, prior.df=10, trend=TRUE, span=NULL, AveLogCPM=NULL, weights=NULL, ...)
```
Arguments

- **y**: matrix of counts or a DGEList object.
- **design**: numeric design matrix, as for `glmFit`.
- **trend**: logical. Should the prior be the trended dispersion (TRUE) or the common dispersion (FALSE)?
- **offset**: offset matrix for the log-linear model, as for `glmFit`. Defaults to the log-effective library sizes.
- **dispersion**: common or trended dispersion estimates, used as an initial estimate for the tagwise estimates.
- **prior.df**: prior degrees of freedom.
- **span**: width of the smoothing window, in terms of proportion of the data set. Default value decreases with the number of tags.
- **AveLogCPM**: numeric vector giving average log2 counts per million for each tag.
- **weights**: optional numeric matrix giving observation weights.
- **...**: other arguments are passed to `dispCoxReidInterpolateTagwise`.

Details

This function implements the empirical Bayes strategy proposed by McCarthy et al (2012) for estimating the tagwise negative binomial dispersions. The experimental conditions are specified by design matrix allowing for multiple explanatory factors. The empirical Bayes posterior is implemented as a conditional likelihood with tag-specific weights, and the conditional likelihood is computed using Cox-Reid approximate conditional likelihood (Cox and Reid, 1987).

The prior degrees of freedom determines the weight given to the global dispersion trend. The larger the prior degrees of freedom, the more the tagwise dispersions are squeezed towards the global trend.

Note that the terms ‘tag’ and ‘gene’ are synonymous here. The function is only named ‘Tagwise’ for historical reasons.

This function calls the lower-level function `dispCoxReidInterpolateTagwise`.

Value

- `estimateGLMTagwiseDisp.DGEList` produces a DGEList object, which contains the tagwise dispersion parameter estimate for each tag for the negative binomial model that maximizes the Cox-Reid adjusted profile likelihood. The tagwise dispersions are simply added to the DGEList object provided as the argument to the function.
- `estimateGLMTagwiseDisp.default` returns a vector of the tagwise dispersion estimates.

Author(s)

Gordon Smyth, Davis McCarthy
**estimateGLMTrendedDisp**

Estimate Trended Dispersion for Negative Binomial GLMs

**Description**

Estimates the abundance-dispersion trend by Cox-Reid approximate profile likelihood.

**Usage**

```r
## S3 method for class 'DGEList'
estimateGLMTrendedDisp(y, design=NULL, method="auto", ...)
```

```r
## Default S3 method:
estimateGLMTrendedDisp(y, design=NULL, offset=NULL, AveLogCPM=NULL,
method="auto", weights=NULL, ...)
```

**Arguments**

- `y`  
a matrix of counts or a DGEList object.
- `design`  
numeric design matrix, as for `glmFit`.

**References**

**See Also**

- `estimateGLMCommonDisp` for common dispersion or `estimateGLMTrendedDisp` for trended dispersion in the context of a generalized linear model.
- `estimateCommonDisp` for common dispersion or `estimateTagwiseDisp` for tagwise dispersions in the context of a multiple group experiment (one-way layout).

**Examples**

```r
y <- matrix(rnbinom(1000,mu=10,size=10),ncol=4)
d <- DGEList(counts=y,group=c(1,1,2,2),lib.size=c(1000:1003))
design <- model.matrix(~group, data=d$samples) # Define the design matrix for the full model
d <- estimateGLMTrendedDisp(d, design, min.n=10)
d <- estimateGLMTagwiseDisp(d, design)
summary(d$tagwise.dispersion)
```
method (low-level function) used to estimated the trended dispersions. Possible values are "auto" (default, switch to "bin.spline" method if the number of genes is greater than 200 and "power" method otherwise), "bin.spline", "bin.loess" (which both result in a call to dispBinTrend), "power" (call to dispCoxReidPowerTrend), or "spline" (call to dispCoxReidSplineTrend).

offset numeric scalar, vector or matrix giving the linear model offsets, as for glmFit.

AveLogCPM numeric vector giving average log2 counts per million for each gene.

weights optional numeric matrix giving observation weights

... other arguments are passed to lower-level functions dispBinTrend, dispCoxReidPowerTrend or dispCoxReidSplineTrend.

Details

Estimates the dispersion parameter for each gene with a trend that depends on the overall level of expression for that gene. This is done for a DGE dataset for general experimental designs by using Cox-Reid approximate conditional inference for a negative binomial generalized linear model for each gene with the unadjusted counts and design matrix provided.

The function provides an object-orientated interface to lower-level functions.

Value

When the input object is a DGEList, estimateGLMTrendedDisp produces a DGEList object, which contains the estimates of the trended dispersion parameter for the negative binomial model according to the method applied.

When the input object is a numeric matrix, it returns a vector of trended dispersion estimates calculated by one of the lower-level functions dispBinTrend, dispCoxReidPowerTrend and dispCoxReidSplineTrend.

**estimateTagwiseDisp**  
*Estimate Empirical Bayes Tagwise Dispersion Values*

**Description**

Estimates tagwise dispersion values by an empirical Bayes method based on weighted conditional maximum likelihood.

**Usage**

```r
## S3 method for class 'DGEList'
estimateTagwiseDisp(y, prior.df=10, trend="movingave", span=NULL, method="grid",
   grid.length=11, grid.range=c(-6,6), tol=1e-06, verbose=FALSE, ...)

## Default S3 method:
estimateTagwiseDisp(y, group=NULL, lib.size=NULL, dispersion, AveLogCPM=NULL,
   prior.df=10, trend="movingave", span=NULL, method="grid", grid.length=11,
   grid.range=c(-6,6), tol=1e-06, verbose=FALSE, ...)
```

**Arguments**

- `y`  
  matrix of counts or a DGEList object.
- `prior.df`  
  prior degrees of freedom.
- `trend`  
  method for estimating dispersion trend. Possible values are "movingave" (default), "loess" and "none".
- `span`  
  width of the smoothing window, as a proportion of the data set.
- `method`  
  method for maximizing the posterior likelihood. Possible values are "grid" (default) for interpolation on grid points or "optimize" to call the function of the same name.
- `grid.length`  
  for method="grid", the number of points on which the interpolation is applied for each tag.
- `grid.range`  
  for method="grid", the range of the grid points around the trend on a log2 scale.
- `tol`  
  for method="optimize", the tolerance for Newton-Rhapson iterations.
- `verbose`  
  logical, if TRUE then diagnostic output is produced during the estimation process.
- `group`  
  vector or factor giving the experimental group/condition for each library.
- `lib.size`  
  numeric vector giving the total count (sequence depth) for each library.
dispersion common dispersion estimate, used as an initial estimate for the tagwise estimates.
AveLogCPM numeric vector giving average log2 counts per million for each tag
... other arguments that are not currently used.

Details
This function implements the empirical Bayes strategy proposed by Robinson and Smyth (2007) for estimating the tagwise negative binomial dispersions. The experimental design is assumed to be a oneway layout with one or more experimental groups. The empirical Bayes posterior is implemented as a conditional likelihood with tag-specific weights.

The prior values for the dispersions are determined by a global trend. The individual tagwise dispersions are then squeezed towards this trend. The prior degrees of freedom determines the weight given to the prior. The larger the prior degrees of freedom, the more the tagwise dispersions are squeezed towards the global trend. If the number of libraries is large, the prior becomes less important and the tagwise dispersions are determined more by the individual tagwise data.

If trend="none", then the prior dispersion is just a constant, the common dispersion. Otherwise, the trend is determined by a moving average (trend="movingave") or loess smoother applied to the tagwise conditional log-likelihood. method="loess" applies a loess curve of degree 0 as implemented in loessByCol.

method="optimize" is not recommended for routine use as it is very slow. It is included for testing purposes.

Note that the terms ‘tag’ and ‘gene’ are synonymous here. The function is only named ‘Tagwise’ for historical reasons.

Value
estimateTagwiseDisp.DGEList adds the following components to the input DGEList object:

prior.df prior degrees of freedom.
prior.n estimate of the prior weight.
tagwise.dispersion numeric vector of the tagwise dispersion estimates.
span width of the smoothing window, in terms of proportion of the data set.

estimateTagwiseDisp.default returns a numeric vector of the tagwise dispersion estimates.

Author(s)
Mark Robinson, Davis McCarthy, Yunshun Chen and Gordon Smyth

References
estimateTrendedDisp

**Description**

Estimates trended dispersion values by an empirical Bayes method.

**Usage**

```r
## S3 method for class 'DGEList'
estimateTrendedDisp(y, method="bin.spline", df=5, span=2/3, ...)
## Default S3 method:
estimateTrendedDisp(y, group=NULL, lib.size=NULL, AveLogCPM=NULL,
method="bin.spline", df=5, span=2/3, ...)
```

**Arguments**

- `y`: matrix of counts or a DGEList object.
- `method`: method used to estimated the trended dispersions. Possible values are "bin.spline", and "bin.loess".
- `df`: integer giving the degrees of freedom of the spline function if "bin.spline" method is used, see `ns` in the splines package. Default is 5.
- `span`: scalar, passed to loess to determine the amount of smoothing for the loess fit when "loess" method is used. Default is 2/3.
- `group`: vector or factor giving the experimental group/condition for each library.
- `lib.size`: numeric vector giving the total count (sequence depth) for each library.
- `AveLogCPM`: numeric vector giving average log2 counts per million for each tag.
- `...`: other arguments that are not currently used.

**Examples**

```r
# True dispersion is 1/5=0.2
y <- matrix(rnbinom(250*4,mu=20,size=5),nrow=250,ncol=4)
dge <- DGEList(counts=y,group=c(1,1,2,2))
dge <- estimateCommonDisp(dge)
dge <- estimateTagwiseDisp(dge)
```
Details

This function takes the binned common dispersion and abundance, and fits a smooth curve through these binned values using either natural cubic splines or loess. From this smooth curve it predicts the dispersion value for each gene based on the gene’s overall abundance. This results in estimates for the NB dispersion parameter which have a dependence on the overall expression level of the gene, and thus have an abundance-dependent trend.

Value

An object of class \texttt{DGEList} with the same components as for \texttt{estimateCommonDisp} plus the trended dispersion estimates for each gene.

Author(s)

Yunshun Chen and Gordon Smyth

See Also

\texttt{estimateCommonDisp} estimates a common value for the dispersion parameter for all genes - should generally be run before \texttt{estimateTrendedDisp}.

Examples

```r
ngenes <- 1000
nlib <- 4
log2cpm <- seq(from=0,to=16,length=ngenes)
lib.size <- 1e7
mu <- 2^log2cpm * lib.size * 1e-6
dispersion <- 1/sqrt(mu) + 0.1
counts <- rnbinom(ngenes*nlib, mu=mu, size=1/dispersion)
counts <- matrix(counts,ngenes,nlib)
y <- DGEList(counts,lib.size=rep(lib.size,nlib))
y <- estimateCommonDisp(y)
y <- estimateTrendedDisp(y)
```

\texttt{exactTest} \hspace{1em} \textit{Exact Tests for Differences between Two Groups of Negative-Binomial Counts}

Description

Compute genewise exact tests for differences in the means between two groups of negative-binomially distributed counts.
Usage

```r
exactTest(object, pair=1:2, dispersion="auto", rejection.region="doubletail",
          big.count=900, prior.count=0.125)
exactTestDoubleTail(y1, y2, dispersion=0, big.count=900)
exactTestBySmallP(y1, y2, dispersion=0)
exactTestByDeviance(y1, y2, dispersion=0)
exactTestBetaApprox(y1, y2, dispersion=0)
```

Arguments

- **object**: an object of class `DGEList`.
- **pair**: vector of length two, either numeric or character, providing the pair of groups to be compared; if a character vector, then should be the names of two groups (e.g. two levels of `object$samples$group`); if numeric, then groups to be compared are chosen by finding the levels of `object$samples$group` corresponding to those numeric values and using those levels as the groups to be compared; if `NULL`, then first two levels of `object$samples$group` (a factor) are used. Note that the first group listed in the pair is the baseline for the comparison—so if the pair is `c("A", "B")` then the comparison is `B - A`, so genes with positive log-fold change are up-regulated in group B compared with group A (and vice versa for genes with negative log-fold change).
- **dispersion**: either a numeric vector of dispersions or a character string indicating that dispersions should be taken from the data object. If a numeric vector, then can be either of length one or of length equal to the number of genes. Allowable character values are "common", "trended", "tagwise" or "auto". Default behavior ("auto" is to use most complex dispersions found in data object).
- **rejection.region**: type of rejection region for two-sided exact test. Possible values are "doubletail", "smallp" or "deviance".
- **big.count**: count size above which asymptotic beta approximation will be used.
- **prior.count**: average prior count used to shrink log-fold-changes. Larger values produce more shrinkage.
- **y1**: numeric matrix of counts for the first the two experimental groups to be tested for differences. Rows correspond to genes and columns to libraries. Libraries are assumed to be equal in size - e.g. adjusted pseudocounts from the output of `equalizeLibSizes`.
- **y2**: numeric matrix of counts for the second of the two experimental groups to be tested for differences. Rows correspond to genes and columns to libraries. Libraries are assumed to be equal in size - e.g. adjusted pseudocounts from the output of `equalizeLibSizes`. Must have the same number of rows as `y1`.

Details

The functions test for differential expression between two groups of count libraries. They implement the exact test proposed by Robinson and Smyth (2008) for a difference in mean between two groups of negative binomial random variables. The functions accept two groups of count libraries,
and a test is performed for each row of data. For each row, the test is conditional on the sum of counts for that row. The test can be viewed as a generalization of the well-known exact binomial test (implemented in binomTest) but generalized to overdispersed counts.

exactTest is the main user-level function, and produces an object containing all the necessary components for downstream analysis. exactTest calls one of the low level functions exactTestDoubleTail, exactTestBetaApprox, exactTestBySmallP or exactTestByDeviance to do the p-value computation. The low level functions all assume that the libraries have been normalized to have the same size, i.e., to have the same expected column sum under the null hypothesis. exactTest equalizes the library sizes using equalizeLibSizes before calling the low level functions.

The functions exactTestDoubleTail, exactTestBySmallP and exactTestByDeviance correspond to different ways to define the two-sided rejection region when the two groups have different numbers of samples. exactTestBySmallP implements the method of small probabilities as proposed by Robinson and Smyth (2008). This method corresponds exactly to binomTest as the dispersion approaches zero, but gives poor results when the dispersion is very large. exactTestDoubleTail computes two-sided p-values by doubling the smaller tail probability. exactTestByDeviance uses the deviance goodness of fit statistics to define the rejection region, and is therefore equivalent to a conditional likelihood ratio test.

Note that rejection.region="smallp" is no longer recommended. It is preserved as an option only for backward compatibility with early versions of edgeR. rejection.region="deviance" has good theoretical statistical properties but is relatively slow to compute. rejection.region="doubletail" is just slightly more conservative than rejection.region="deviance", but is recommended because of its much greater speed. For general remarks on different types of rejection regions for exact tests see Gibbons and Pratt (1975).

exactTestBetaApprox implements an asymptotic beta distribution approximation to the conditional count distribution. It is called by the other functions for rows with both group counts greater than big.count.

Value

exactTest produces an object of class DGEExact containing the following components:

- table: data frame containing columns for the log2-fold-change (logFC), the average log2-counts-per-million (logCPM), and the two-sided p-value (PValue).
- comparison: character vector giving the names of the two groups being compared.
- genes: data frame containing annotation for each gene; taken from object.

The low-level functions, exactTestDoubleTail etc, produce a numeric vector of genewise p-values, one for each row of y1 and y2.

Description

Expand scalar or vector to a matrix.

Usage

expandAsMatrix(x, dim=NULL, byrow=TRUE)

Arguments

x
scalar, vector, matrix or CompressedMatrix.
dim
integer vector of length 2 specifying the required dimensions of the output matrix.
byrow
logical scalar specifying if matrix should be filled by columns or rows for a vector x.

Details

This function expands a scalar, row/column vector or CompressedMatrix to be a matrix of dimensions dim. It is used internally in edgeR to convert offsets, weights and other values to a matrix for consistent handling. If dim is NULL, the function is equivalent to calling as.matrix(x).

If x is a vector, its length must match one of the output dimensions. The matrix will then be filled by repeating the matrix across the matching dimension. For example, if length(x)==dim[1], the matrix will be filled such that each row contains x. If both dimensions match, filling is determined by byrow, with filling by rows as the default.

If x CompressedMatrix object, the size of any non-repeated dimensions must be consistent with corresponding output dimension. The byrow argument will be ignored as the repeat specifications will dictate how expansion should be performed. See ?CompressedMatrix for more details.
**Value**

Numeric matrix of dimension dim.

**Author(s)**

Gordon Smyth

**Examples**

expandAsMatrix(1:3,c(4,3))
expandAsMatrix(1:4,c(4,3))

---

**featureCounts2DGEList**  
*Convert featureCounts object to a DGEList*

**Description**

Converts the list output by Rsubread::featureCounts to a DGEList object.

**Usage**

featureCounts2DGEList(x)

**Arguments**

|x| a list produced by Rsubread::featureCounts. |

**Details**

Rsubread's `featureCounts` function counts reads by features (typically exons or genomic intervals) or meta-features (typically genes). It may also count reads crossing exon-exon junctions or reads internal to exons. This function assembles all the read counts output by `featureCounts` into a DGEList, ensuring unique row.names where appropriate. The proportion of reads assigned to features is also stored.

**Value**

A DGEList data object.

**Author(s)**

Gordon Smyth.

**See Also**

[DGEList-class](#)
Description

Determine which genes have sufficiently large counts to be retained in a statistical analysis.

Usage

```r
## S3 method for class 'DGEList'
filterByExpr(y, design = NULL, group = NULL, lib.size = NULL, ...)
## S3 method for class 'SummarizedExperiment'
filterByExpr(y, design = NULL, group = NULL, lib.size = NULL, ...)
## Default S3 method:
filterByExpr(y, design = NULL, group = NULL, lib.size = NULL,
min.count = 10, min.total.count = 15, large.n = 10, min.prop = 0.7, ...)
```

Arguments

- `y`: matrix of counts, or a DGEList object, or a SummarizedExperiment object.
- `design`: design matrix. Ignored if group is not NULL.
- `group`: vector or factor giving group membership for a oneway layout, if appropriate.
- `lib.size`: library size, defaults to `colSums(y)`.
- `min.count`: numeric. Minimum count required for at least some samples.
- `min.total.count`: numeric. Minimum total count required.
- `large.n`: integer. Number of samples per group that is considered to be “large”.
- `min.prop`: numeric. In large sample situations, the minimum proportion of samples in a group that a gene needs to be expressed in. See Details below for the exact formula.
- `...`: any other arguments. For the DGEList and SummarizedExperiment methods, other arguments will be passed to the default method. For the default method, other arguments are not currently used.

Details

This function implements the filtering strategy that was described informally by Chen et al (2016). Roughly speaking, the strategy keeps genes that have at least `min.count` reads in a worthwhile number samples.

More precisely, the filtering keeps genes that have `CPM >= CPM.cutoff` in `MinSampleSize` samples, where `CPM.cutoff = min.count/median(lib.size)*1e6` and `MinSampleSize` is the smallest group sample size or, more generally, the minimum inverse leverage computed from the design matrix.
If all the group samples sizes are large, then the above filtering rule is relaxed slightly. If \( \text{MinSampleSize} > \text{large.n} \), then genes are kept if \( \text{CPM} \geq \text{CPM.cutoff} \) in \( k \) samples where \( k = \text{large.n} + (\text{MinSampleSize} - \text{large.n}) \times \text{min.prop} \). This rule requires that genes are expressed in at least \( \text{min.prop} \times \text{MinSampleSize} \) samples, even when \( \text{MinSampleSize} \) is large.

In addition, each kept gene is required to have at least \( \text{min.total.count} \) reads across all the samples.

**Value**

Logical vector of length \( \text{nrow}(y) \) indicating which rows of \( y \) to keep in the analysis.

**Author(s)**

Gordon Smyth

**References**

**Examples**

```r
## Not run:
keep <- filterByExpr(y, design)
y <- y[keep,]
## End(Not run)
```

---

**getCounts**

*Extract Specified Component of a DGEList Object*

**Description**

\( \text{getCounts}(y) \) returns the matrix of read counts \( y\text{$counts} \).

\( \text{getOffset}(y) \) returns offsets for the log-linear predictor account for sequencing depth and possibly other normalization factors. Specifically it returns the matrix \( y\text{$offset} \) if it is non-null, otherwise it returns the log product of \( \text{lib.size} \) and \( \text{norm.factors} \) from \( y\text{$samples} \).

\( \text{getDispersion}(y) \) returns the most complex dispersion estimates (common, trended or genewise) found in \( y \).

**Usage**

\( \text{getCounts}(y) \)
\( \text{getOffset}(y) \)
\( \text{getDispersion}(y) \)
**getNormLibSizes**

**Arguments**

- **y**
  
  A `DGEList` object containing (at least) the elements: `counts` (table of raw counts), `group` (factor indicating group) and `lib.size` (numeric vector of library sizes).

**Value**

- `getCounts` returns the matrix of counts.
- `getOffset` returns a numeric matrix or vector.
- `getDispersion` returns vector of dispersion values.

**Author(s)**

Mark Robinson, Davis McCarthy, Gordon Smyth

**See Also**

- `DGEList-class`

**Examples**

```r
# generate raw counts from NB, create list object
y <- matrix(rnbinom(20, size=5, mu=10), 5, 4)
d <- DGEList(counts=y, group=c(1,1,2,2), lib.size=1001:1004)
getCounts(d)
getOffset(d)
d <- estimateCommonDisp(d)
getDispersion(d)
```

---

**getNormLibSizes** | **Effective Library Sizes**

---

**Description**

Extract effective (normalized) library sizes.

**Usage**

```r
## Default S3 method:
getNormLibSizes(y, log = FALSE, ...)
```

**Arguments**

- **y**
  
  A object of class `DGEList`, `DGEGLM` or `DGELRT`. Alternatively a numeric matrix or an object that can be coerced to a numeric matrix.

- **log**
  
  Logical, if TRUE then the library sizes are return on the natural log scale.

- **...**
  
  Other arguments are not currently used.
getPriorN

**Details**

This function extracts normalized library sizes, equal to the original library sizes multiplied by the corresponding normalization factors, from an edgeR data object or fitted model object.

If the object contains a row-specific offsets (i.e., a non-sparse matrix of offsets), then the offsets for the first row are returned.

**Value**

A numeric matrix of effective (normalized) library sizes. If `log=TRUE`, then natural log values are returned, equal to library size offsets for a NB log-linear model.

**Author(s)**

Gordon Smyth

**See Also**

`normLibSizes`

**Examples**

```r
ngenes <- 100
nsamples <- 4
y <- DGEList(counts=matrix(rnbinom(ngenes*nsamples,size=1,mu=10),ngenes,nsamples))
y <- normLibSizes(y)
data.frame(y$samples, eff.lib.size=getNormLibSizes(y))
```

---

getPriorN

*Get a Recommended Value for Prior N from DGEList Object*

**Description**

Returns the `lib.size` component of the `samples` component of DGEList object multiplied by the `norm.factors` component

**Usage**

`getPriorN(y, design=NULL, prior.df=20)`

**Arguments**

- `y` a DGEList object with (at least) elements `counts` (table of unadjusted counts) and `samples` (data frame containing information about experimental group, library size and normalization factor for the library size)
getPriorN

numeric matrix (optional argument) giving the design matrix for the GLM that is to be fit. Must be of full column rank. If provided, design is used to determine the number of parameters to be fit in the statistical model and therefore the residual degrees of freedom. If left as the default (NULL) then the y$samples$group element of the DGEList object is used to determine the residual degrees of freedom.

prior.df numeric scalar giving the weight, in terms of prior degrees of freedom, to be given to the common parameter likelihood when estimating genewise dispersion estimates.

Details

When estimating genewise dispersion values using estimateTagwiseDisp or estimateGLMTagwiseDisp we need to decide how much weight to give to the common parameter likelihood in order to smooth (or stabilize) the dispersion estimates. The best choice of value for the prior.n parameter varies between datasets depending on the number of samples in the dataset and the complexity of the model to be fit. The value of prior.n should be inversely proportional to the residual degrees of freedom. We have found that choosing a value for prior.n that is equivalent to giving the common parameter likelihood 20 degrees of freedom generally gives a good amount of smoothing for the genewise dispersion estimates. This function simply recommends an appropriate value for prior.n—to be used as an argument for estimateTagwiseDisp or estimateGLMTagwiseDisp—given the experimental design at hand and the chosen prior degrees of freedom.

Value

getPriorN returns a numeric scalar

Examples

# generate raw counts from NB, create list object
y<-matrix(rnbinom(20,size=1,mu=10),nrow=5)
d<-DGEList(counts=y,group=rep(1:2,each=2),lib.size=rep(c(1000:1001),2))
getPriorN(d)
gini

Gini dispersion index

Description

Gini index for each column of a matrix.

Usage

gini(x)

Arguments

x

a non-negative numeric matrix, or an object that can be coerced to such a matrix by as.matrix.

Details

The Gini coefficient or index is a measure of inequality or diversity. It is zero if all the values of x are equal. It reaches a maximum value of 1/nrow(x) when all values are zero except for one.

The Gini index is only interpretable for non-negative quantities. It is not meaningful if x contains negative values.

Value

Numeric vector of length ncol(x).

Author(s)

Gordon Smyth

References

Examples

x <- matrix(rpois(20, lambda=5), 10, 2)
gini(x)
glmFit

Genewise Negative Binomial Generalized Linear Models

Description

Fit a negative binomial generalized log-linear model to the read counts for each gene.

Usage

## Default S3 method:
glmFit(y, design=NULL, dispersion=NULL, offset=NULL, lib.size=NULL, weights=NULL, prior.count=0.125, start=NULL, ...)
## S3 method for class 'DGEList'
glmFit(y, design=NULL, dispersion=NULL, prior.count=0.125, start=NULL, ...)
## S3 method for class 'SummarizedExperiment'
glmFit(y, design=NULL, dispersion=NULL, prior.count=0.125, start=NULL, ...)

Arguments

y
a matrix of counts or a DGEList object or a SummarizedExperiment containing counts. Rows represent genes and columns represent samples.
design
numeric matrix giving the design matrix for the genewise linear models. Must be of full column rank. Defaults to a single column of ones, equivalent to treating the columns as replicate libraries.
dispersion
numeric scalar, vector or matrix of negative binomial dispersions. Can be a common value for all genes, a vector of dispersion values with one for each gene, or a matrix of dispersion values with one for each observation. If NULL will be extracted from y, with order of precedence: genewise dispersion, trended dispersions, common dispersion.
offset
numeric matrix of same size as y giving offsets for the log-linear models. Can be a scalar or a vector of length ncol(y), in which case it is expanded out to a matrix.
weights
optional numeric matrix giving prior weights for the observations (for each library and gene) to be used in the GLM calculations.
lib.size
numeric vector of length ncol(y) giving library sizes. Only used if offset=NULL, in which case offset is set to log(lib.size). Defaults to colSums(y).
prior.count
average prior count to be added to observation to shrink the estimated log-fold-changes towards zero.
start
optional numeric matrix of initial estimates for the linear model coefficients.
...
other arguments are passed to lower level fitting functions.
Details

Implements generalized linear model (GLM) methods developed by McCarthy et al (2012). Specifically, glmFit fits genewise negative binomial GLMs, all with the same design matrix but possibly different dispersions, offsets and weights. When the design matrix defines a one-way layout, or can be re-parametrized to a one-way layout, the GLMs are fitting very quickly using mglmOneGroup. Otherwise the default fitting method, implemented in mglmLevenberg, uses a Fisher scoring algorithm with Levenberg-style damping.

Positive prior.count values cause the returned coefficients to be shrunk in such a way that fold-changes between the treatment conditions are decreased and infinite fold-changes are avoided (Phipson, 2013). Larger prior.count values cause more shrinkage. Coefficient shrinkage does not affect the likelihood ratio tests or p-values.

Value

An object of class DGEGLM containing components counts, samples, genes and abundance from y plus the following new components:

- **design**: design matrix as input.
- **weights**: matrix of weights as input.
- **df.residual**: numeric vector of residual degrees of freedom, one for each gene.
- **offset**: numeric matrix of linear model offsets.
- **dispersion**: vector of dispersions used for the fit.
- **coefficients**: numeric matrix of estimated coefficients from the glm fits, on the natural log scale, of size nrow(y) by ncol(design).
- **unshrunk.coefficients**: numeric matrix of estimated coefficients from the glm fits when no log-fold-changes shrinkage is applied, on the natural log scale, of size nrow(y) by ncol(design).
  It exists only when prior.count is not 0.
- **fitted.values**: matrix of fitted values from glm fits, same number of rows and columns as y.
- **deviance**: numeric vector of deviances, one for each gene.

### glmLRT

**Genewise Likelihood Ratio Tests**

**Description**

Given genewise generalized linear model fits, conduct likelihood ratio tests for a given coefficient or coefficient contrast.

**Usage**

```r
glmLRT(glmfit, coef=ncol(glmfit$design), contrast=NULL)
```
### Arguments

- **glmfit**: a DGEGLM object, usually output from glmFit.
- **coef**: integer or character vector indicating which coefficients of the linear model are to be tested equal to zero. Values must be columns or column names of design. Defaults to the last coefficient. Ignored if contrast is specified.
- **contrast**: numeric vector or matrix specifying one or more contrasts of the linear model coefficients to be tested equal to zero. If a matrix, then rows correspond to the columns of design and columns are contrasts. If non-NULL, then takes precedence over coef.

### Details

Using genewise GLMs from glmFit, glmLRT conducts likelihood ratio tests for one or more coefficients in the linear model. If contrast is NULL, the null hypothesis is that all the coefficients specified by coef are equal to zero. If contrast is non-NULL, then the null hypothesis is that the specified contrasts of the coefficients are equal to zero. For example, contrast = c(0,1,-1), assuming there are three coefficients, would test the hypothesis that the second and third coefficients are equal. If contrast is a matrix, then each column is a contrast and the null hypothesis is that all the contrasts are equal to zero.

### Value

An object of class DGELRT with the same components as for glmFit plus the following:

- **table**: data frame with the same rows as y containing the log2-fold-changes, likelihood ratio statistics and p-values, ready to be displayed by topTags.
- **comparison**: character string describing the coefficient or the contrast being tested.

The data frame table contains the following columns:

- **logFC**: log2-fold change of expression between conditions being tested.
- **logCPM**: average log2-counts per million, the average taken over all libraries in y.
- **LR**: likelihood ratio statistics.
- **PValue**: p-values.

glmQLFit

Genewise Negative Binomial Generalized Linear Models with Quasi-
Dispersion Estimation

Description

Fit a negative binomial generalized log-linear model to the read counts for each gene. Estimate the
genewise quasi-dispersions with empirical Bayes moderation.

Usage

## Default S3 method:
glmQLFit(y, design = NULL, dispersion = NULL, offset = NULL, lib.size = NULL,
weights = NULL, abundance.trend = TRUE, AveLogCPM = NULL,
covariate.trend = NULL, robust = FALSE, winsor.tail.p = c(0.05, 0.1),
legacy = TRUE, top.proportion = 0.05, ...)

## S3 method for class 'DGEList'
glmQLFit(y, design = NULL, dispersion = NULL, abundance.trend = TRUE,
robust = FALSE, winsor.tail.p = c(0.05, 0.1),
legacy = TRUE, top.proportion = 0.05, ...)

## S3 method for class 'SummarizedExperiment'
glmQLFit(y, design = NULL, dispersion = NULL, abundance.trend = TRUE,
robust = FALSE, winsor.tail.p = c(0.05, 0.1),
legacy = TRUE, top.proportion = 0.05, ...)

Arguments

y
a matrix of counts or a DGEList object or a SummarizedExperiment containing
counts. Rows represent genes and columns represent samples.
design
numeric matrix giving the design matrix for the genewise linear models.
dispersion
negative binomial dispersions. Can be a single value, or a vector of length
nrow(y), or a matrix of the same size as y. If NULL and legacy=TRUE, then
will be extracted from the DGEList object y. The trended dispersions will be
extracted if present, otherwise common dispersion, or a constant value of 0.05
is neither is present. If NULL and legacy=FALSE, then will be estimated using
the top.proportion of most highly expressed genes.
offset
numeric matrix of same size as y giving offsets for the log-linear models. Can
be a single value, or a vector of length ncol(y), or a matrix of the same size as
y. If NULL, then will be computed by getOffset(y).
lib.size
numeric vector of length ncol(y) giving library sizes. Only used if offset=NULL,
in which case offset is set to log(lib.size). Defaults to colSums(y).
weights
numeric matrix of same size as y giving glm weights. If NULL, will be set to
unity for all observations.
Details

glmQLFit and glmQLFTest implement the quasi-likelihood (QL) methods of Lund et al (2012) with some enhancements and with slightly different glm, trend and FDR methods. See Lun et al (2016) or Chen et al (2016) for tutorials describing the use of glmQLFit and glmQLFTest as part of a complete analysis pipeline. Another case study using glmQLFit and glmQLFTest is given in Section 4.7 of the edgeR User's Guide.

glmQLFit is similar to glmFit except that it also estimates a quasi-dispersion (QL-dispersion) for each gene. It calls the limma function squeezeVar to conduct empirical Bayes moderation of the genewise QL-dispersions. If robust=TRUE, then the robust hyperparameter estimation features of squeezeVar are used (Phipson et al, 2016). If abundance.trend=TRUE, then a prior trend is estimated based on the average logCPMs. If covariate.trend=TRUE and robust=FALSE, then the new QL-dispersion estimation method with adjusted deviances is used.

glmQLFit gives special attention to handling of small counts and zero counts. When legacy=TRUE, the function uses the method of Lun and Smyth (2017) to adjust the residual degrees of freedom when fitted values of zero provide no useful residual degrees of freedom for estimating the QL dispersion. The usual residual degrees of freedom are returned as df.residual while the adjusted residual degrees of freedom are returned as df.residuals.zeros.

If legacy=FALSE, then a more comprehensive adjustment for small counts is used. The new method adjusts both the residual deviances and the residual degrees of freedom to improve the accuracy of the quasi-dispersion estimates even for very small counts. With this new method, the residual deviance is no longer equal to the usual residual deviance from generalized linear model theory and the residual degrees of freedom are no longer integers. With the new method, the glmQLFTest function should give good error rate control even for data with many small counts. The legacy=FALSE method was introduced in edgeR 4.0.0 with the Bioconductor 3.18 release. Setting legacy=TRUE will reproduce earlier results as for Bioconductor 3.16.
glmQLFit requires the NB dispersion to be pre-specified when legacy=TRUE but not when legacy=FALSE. In the new pipeline, the NB dispersion will be automatically estimated by glmQLFit whenever dispersion=NULL.

Value

glmQLFit with legacy=TRUE produces an object of class DGEGLM with the same components as produced by glmFit, plus:

- df.residual.zeros: numeric vector of effective residual degrees of freedom for each gene, after accounting for treatment groups with all zero counts.
- df.prior: numeric vector of prior degrees of freedom for the QL-dispersions. Has length nrow(y) if robust=TRUE, otherwise length 1.
- var.prior: numeric vector giving prior value for the QL-dispersions. Has length nrow(y) if abundance.trend=TRUE, otherwise length 1.
- var.post: numeric vector of posterior genewise QL-dispersions.

glmQLFit with legacy=FALSE produces an object of class DGEGLM with the same components as produced by glmFit, plus:

- leverage: numeric matrix of leverages for the genewise glms.
- unit.deviance.adj: numeric matrix of adjusted unit deviances for the genewise glms.
- unit.df.adj: numeric matrix of adjusted degrees of freedom for the unit deviances.
- df.residual.adj: numeric vector of adjusted residual degrees of freedom for each gene.
- df.prior: numeric vector of prior degrees of freedom for the QL-dispersions. Has length nrow(y) if robust=TRUE, otherwise length 1.
- var.prior: numeric vector giving prior value the QL-dispersions. Has length nrow(y) if abundance.trend=TRUE, otherwise length 1.
- var.post: numeric vector of posterior genewise QL-dispersions.
- average.ql.dispersion: average QL-dispersion, used to scale the NB dispersion after estimating the QL-dispersions.

Note

The negative binomial dispersions dispersion supplied to glmQLFit must be based on a global model, that is, they must be either trended or common dispersions. It is not correct to supply genewise dispersions because glmQLFit estimates gene-specific variability using the QL dispersions.

```

---

### glmQLFTest

**Quasi-Likelihood F-Tests**

**Description**

Conduct genewise quasi F-tests for a given coefficient or coefficient contrast.

**Usage**

```r
glmQLFTest(glmfit, coef = ncol(glmfit$design), contrast = NULL,
poisson.bound = TRUE)
```

**Arguments**

- `glmfit`: a DGEGLM object, usually output from `glmQLFit`.
- `coef`: integer or character index vector indicating which coefficients of the linear model are to be tested equal to zero. Ignored if `contrast` is not `NULL`.
- `contrast`: numeric vector or matrix specifying one or more contrasts of the linear model coefficients to be tested equal to zero.
- `poisson.bound`: logical, if TRUE then the p-value returned will never be less than would be obtained for a likelihood ratio test with NB-dispersion equal to 0 and QL-dispersion equal to 1. Only uses when `legacy=TRUE`.

**Details**

`glmQLFTest` is typically used after `glmQLFit`. The two functions implement the quasi-likelihood (QL) methods of Lund et al (2012) with some enhancements and with slightly different GLM, trend and FDR methods. See Lun et al (2016) or Chen et al (2016) for tutorials describing the use of `glmQLFit` and `glmQLFTest` as part of a complete analysis pipeline. Another case study using `glmQLFit` and `glmQLFTest` is given in Section 4.7 of the edgeR User’s Guide.

`glmQLFTest` is similar to `glmLRT` except that it replaces likelihood ratio tests with empirical Bayes quasi-likelihood F-tests. The p-values from `glmQLFTest` are always greater than or equal to those that would be obtained from `glmLRT` using the same negative binomial dispersions.

**Value**

An object of class `DGELRT` with the same components as produced by `glmLRT`, except that the `table$LR` column becomes `table$F` and contains quasi-likelihood F-statistics. It also stores `df.total`, a numeric vector containing the denominator degrees of freedom for the F-test, equal to `df.prior + df.residual.zeros`.

*topTags* displays results from *glmQLFTest*.

*plotQLDisp* can be used to visualize the distribution of QL dispersions after EB shrinkage from *glmQLFit*.

The QuasiSeq package gives an alternative implementation of the Lund et al (2012) methods.

Examples

```r
# See glmQLFit for an example using glmQLFTest
```
**Arguments**

- **glmfit**
  - A DGEGLM object, usually output from glmFit or glmQLFit.

- **coef**
  - Integer or character vector indicating which coefficients of the linear model are to be tested equal to zero. Values must be columns or column names of `design`. Defaults to the last coefficient. Ignored if `contrast` is specified.

- **contrast**
  - Numeric vector specifying the contrast of the linear model coefficients to be tested against the log2-fold-change threshold. Length must equal to the number of columns of `design`. If specified, then takes precedence over `coef`.

- **lfc**
  - Numeric scalar specifying the absolute value of the log2-fold change threshold above which differential expression is to be considered.

- **null**
  - Character string, choices are "worst.case" or "interval". If "worst.case", then the null hypothesis assumes that the true logFC is on the boundary of the possible values, either at `lfc` or `-lfc`, whichever gives the largest p-value. This gives the most conservative results. If "interval", then the null hypotheses assumes the true logFC to belong to a bounded interval of possible values.

**Details**

`glmTreat` implements a test for differential expression relative to a minimum required fold-change threshold. Instead of testing for genes which have log-fold-changes different from zero, it tests whether the log2-fold-change is greater than `lfc` in absolute value. `glmTreat` is analogous to the TREAT approach developed by McCarthy and Smyth (2009) for microarrays.

Note that the `lfc` testing threshold used to define the null hypothesis is not the same as a log2-fold-change cutoff, as the observed log2-fold-change needs to substantially larger than `lfc` for the gene to be called as significant. In practice, modest values for `lfc` such as \( \log_2(1.1) \), \( \log_2(1.2) \) or \( \log_2(1.5) \) are usually the most useful. In practice, setting `lfc=\log_2(1.2)` or `lfc=\log_2(1.5)` will usually cause most differentially expressed genes to have estimated fold-changes of 2-fold or greater, depending on the sample size and precision of the experiment.

Note also that `glmTreat` constructs test statistics using the unshrunk log2-fold-changes(`unshrunk.logFC`) rather than the log2-fold-changes that are usually reported (`logFC`). If no shrinkage has been applied to the log-fold-changes, i.e., the glms were fitted with `prior.count=0`, then `unshrunk.logFC` and `logFC` are the same and the former is omitted from the output object.

`glmTreat` detects whether `glmfit` was produced by `glmFit` or `glmQLFit`. In the former case, it conducts a modified likelihood ratio test (LRT) against the fold-change threshold. In the latter case, it conducts a quasi-likelihood (QL) F-test against the threshold.

If `lfc=0`, then `glmTreat` is equivalent to `glmLRT` or `glmQLFTest`, depending on whether likelihood or quasi-likelihood is being used.

`glmTreat` with positive `lfc` gives larger p-values than would be obtained with `lfc=0`. If `null="worst.case"`, then `glmTreat` conducts a test closely analogous to the `treat` function in the limma package. This conducts a test if which the null hypothesis puts the true logFC on the boundary of the \([-lfc,lfc]\) interval closest to the observed logFC. If `null="interval"`, then the null hypotheses assumes an interval of possible values for the true logFC. This approach is somewhat less conservative.

Note that, unlike other edgeR functions such as `glmLRT` and `glmQLFTest`, `glmTreat` can only accept a single contrast. If `contrast` is a matrix with multiple columns, then only the first column will be used.
glmTreat produces an object of class DGELRT with the same components as for glmfit plus the following:

- lfc: absolute value of the specified log2-fold-change threshold.
- table: data frame with the same rows as glmfit containing the log2-fold-changes, average log2-counts per million and p-values, ready to be displayed by topTags.
- comparison: character string describing the coefficient or the contrast being tested.

The data frame table contains the following columns:

- logFC: shrunk log2-fold-change of expression between conditions being tested.
- unshrunk.logFC: unshrunk log2-fold-change of expression between conditions being tested. Exists only when prior.count is not equal to 0 for glmfit.
- logCPM: average log2-counts per million, the average taken over all libraries.
- PValue: p-values.

Note

glmTreat was previously called treatDGE in edgeR versions 3.9.10 and earlier.

**Gene Ontology or KEGG Analysis of Differentially Expressed Genes**

---

**Description**

Test for over-representation of gene ontology (GO) terms or KEGG pathways in the up and down differentially expressed genes from a linear model fit.

**Usage**

```r
## S3 method for class 'DGELRT'
goana(de, geneid = rownames(de), FDR = 0.05, trend = FALSE, ...)
## S3 method for class 'DGELRT'
kegga(de, geneid = rownames(de), FDR = 0.05, trend = FALSE, ...)
```

**Arguments**

- **de**
  - an DGELRT or DGEExact object.

- **geneid**
  - gene IDs. Either a character vector of length nrow(de) or the name of the column of de$genes containing the Gene IDs.

- **FDR**
  - false discovery rate cutoff for differentially expressed genes. Numeric value between 0 and 1.

- **trend**
  - adjust analysis for gene length or abundance? Can be logical, or a numeric vector of covariate values, or the name of the column of de$genes containing the covariate values. If TRUE, then de$AveLogCPM is used as the covariate.

- **...**
  - any other arguments are passed to goana.default or kegga.default.

**Details**

goana performs Gene Ontology enrichment analyses for the up and down differentially expressed genes from a linear model analysis. kegga performs the corresponding analysis for KEGG pathways.

The argument de should be a fitted model object created by glmLRT, glmTreat, glmQLFTest or exactTest.

For goana, the gene IDs must be Entrez Gene IDs. These can be supplied either as row.names of de or as a column of de$genes. In the latter case, the column name containing the Entrez IDs is given
by geneid. Alternatively, if the Entrez IDs are not part of the de object, then they can be supplied as a vector argument to geneid.

For kegga, gene IDs other than Entrez Gene IDs are supported for some species. See kegga.default for more information.

If trend=FALSE, the function computes one-sided hypergeometric tests equivalent to Fisher’s exact test.

If trend=TRUE or a covariate is supplied, then a trend is fitted to the differential expression results and the method of Young et al (2010) is used to adjust for this trend. The adjusted test uses Wallenius’ noncentral hypergeometric distribution.

Value

goana produces a data.frame with a row for each GO term and the following columns:

- **Term**: GO term.
- **Ont**: ontology that the GO term belongs to. Possible values are "BP", "CC" and "MF".
- **N**: Number of genes in the GO term.
- **Up**: number of up-regulated differentially expressed genes.
- **Down**: number of down-regulated differentially expressed genes.
- **P.Up**: p-value for over-representation of GO term in up-regulated genes.
- **P.Down**: p-value for over-representation of GO term in down-regulated genes.

The row names of the data frame give the GO term IDs.

kegga produces a data.frame as above except that the rownames are KEGG pathway IDs, Term become Path and there is no Ont column.

Note

This is the help page for goana when de is an edgeR fitted model object. See ?goana for other possible input types.

topGO(go, ont="BP", sort="up")
topGO(go, ont="BP", sort="down")
## End(Not run)
```

---

**gof**

**Goodness of Fit Tests for Multiple GLM Fits**

**Description**

Conducts deviance goodness of fit tests for each fit in a DGEGLM object

**Usage**

```r
gof(glmfit, pcutoff = 0.1, adjust = "holm", plot = FALSE, 
    main = "qq-plot of residual deviances", ...)
```

**Arguments**

- `glmfit`:
  a DGEGLM object containing results from fitting NB GLMs to genes in a DGE dataset with a global dispersion model. Usually this is output from glmFit.

- `pcutoff`:
  scalar giving the cut-off value for the Holm-adjusted p-value. Genes with Holm-adjusted p-values lower than this cutoff value are flagged as ‘dispersion outlier’ genes.

- `adjust`:
  method used to adjust goodness of fit p-values for multiple testing.

- `plot`:
  logical, if TRUE a qq-plot is produced.

- `main`:
  character, title for the plot.

- `...`:
  other arguments are passed to qqnorm.

**Details**

This function is useful for evaluating the adequacy of a global dispersion model, such as a constant or trended dispersion. If plot=TRUE, then it produces a qq-plot similar to those in Figure 2 of McCarthy et al (2012).

**Value**

A list with the following components:

- `gof.statistics`:
  numeric vector of deviance statistics, which are the statistics used for the goodness of fit test.
gof.pvalues numeric vector of p-values providing evidence of poor fit; computed from the chi-square distribution on the residual degrees of freedom from the GLM fits.

outlier logical vector indicating whether or not each gene is a ‘dispersion outlier’ (i.e., the model fit is poor for that gene indicating that the dispersion estimate is not good for that gene).

df scalar, the residual degrees of freedom from the GLM fit for which the goodness of fit statistics have been computed. Also the degrees of freedom for the goodness of fit statistics for the LR (chi-square) test for significance.

If plot=TRUE, then a plot is also produced on the current graphics device.

Note
This function should not be used with tagwise estimated dispersions such as those from estimateGLMTagwiseDisp or estimateDisp. glmfit should contain trended or constant dispersions.

Examples

```r
nlibs <- 3
genenes <- 100
dispersion.true <- 0.1

# Make first gene respond to covariate x
x <- 0:2
design <- model.matrix(~x)
beta.true <- cbind(Beta1=2,Beta2=c(2,rep(0,ngenenes-1)))
mu.true <- 2^(beta.true %*% t(design))

# Generate count data
y <- rnbinom(ngenenes*nlibs,mu=mu.true,size=1/dispersion.true)
y <- matrix(y,ngenenes,nlibs)
colnames(y) <- c("x0","x1","x2")
rownames(y) <- paste("gene",1:ngenenes,sep=".")
d <- DGEList(y)

# Normalize
```
```r
d <- normLibSizes(d)

# Fit the NB GLMs
fit <- glmFit(d, design, dispersion=dispersion.true)
# Check how good the fit is for each gene
gof(fit)
```

---

**goodTuring**

*Good-Turing Frequency Estimation*

**Description**

Non-parametric empirical Bayes estimates of the frequencies of observed (and unobserved) species.

**Usage**

```r
goodTuring(x, conf=1.96)
goodTuringPlot(x)
goodTuringProportions(counts)
```

**Arguments**

- `x` numeric vector of non-negative integers, representing the observed frequency of each species.
- `conf` confidence factor, as a quantile of the standard normal distribution, used to decide for what values the log-linear relationship between frequencies and frequencies of frequencies is acceptable.
- `counts` matrix of counts

**Details**

Observed counts are assumed to be Poisson distributed. Using a non-parametric empirical Bayes strategy, the algorithm evaluates the posterior expectation of each species mean given its observed count. The posterior means are then converted to proportions. In the empirical Bayes step, the counts are smoothed by assuming a log-linear relationship between frequencies and frequencies of frequencies. The fundamentals of the algorithm are from Good (1953). Gale and Sampson (1995) proposed a simplified algorithm with a rule for switching between the observed and smoothed frequencies, and it is Gale and Sampson’s simplified algorithm that is implemented here. The number of zero values in `x` is not used as part of the algorithm, but is returned by this function.

Sampson gives a C code version on his webpage at [http://www.grsampson.net/RGoodTur.html](http://www.grsampson.net/RGoodTur.html) which gives identical results to this function.

`goodTuringPlot` plots log-probability (i.e., log frequencies of frequencies) versus log-frequency.

`goodTuringProportions` runs `goodTuring` on each column of data, then uses the results to predict the proportion of each gene in each library.
Value

goodTuring returns a list with components

count      observed frequencies, i.e., the unique positive values of \( x \)
\( n \)       frequencies of frequencies
\( n_0 \)   frequency of zero, i.e., number of zeros found in \( x \)
proportion estimated proportion of each species given its count
\( P_0 \)  estimated combined proportion of all undetected species

goodTuringProportions returns a matrix of proportions of the same size as counts.

Author(s)

Aaron Lun and Gordon Smyth, adapted from Sampson’s C code from http://www.grsampson.net/RGoodTur.html

References

Examples

```r
# True means of observed species
lambda <- rnorm(10000, mu=2, size=1/10)
lambda <- lambda[lambda>1]

# Observed frequencies
Ntrue <- length(lambda)
x <- rpois(Ntrue, lambda=lambda)
freq <- goodTuring(x)
goodTuringPlot(x)
```

description

Retrieve the first or last parts of a DGEList, DGEExat, DGEGLM, DGELRT or TopTags object.

Usage

```r
## S3 method for class 'DGEList'
head(x, n = 6L, ...)
## S3 method for class 'DGEList'
tail(x, n = 6L, ...)
```
loessByCol

Arguments

x  
an object of class DGEList, DGEEexact, DGEGLM, DGELRT or TopTags.

n  
a single integer. If positive or zero, number rows of resulting object. If negative, all but the n last/first rows of x.

...  
other arguments are not currently used.

Details

head (tail) returns the first (last) n rows when n >= 0 or all but the last (first) n rows when n < 0.

Value

An object like x but generally with fewer rows.

Author(s)

Gordon Smyth

See Also

head in the utils package or head.EList in the limma package.

Examples

Counts <- matrix(rpois(40,lambda=10),20,2)  
rownames(Counts) <- paste0("Gene",1:20)  
colnames(Counts) <- c("A","B")  
y <- DGEList(Counts)  
head(y)  
tail(y)

loessByCol  
Locally Weighted Mean By Column

Description

Smooth columns of matrix by non-robust loess curves of degree 0.

Usage

loessByCol(y, x=NULL, span=0.5)  
locfitByCol(y, x=NULL, weights=1, span=0.5, degree=0)
makeCompressedMatrix

Arguments

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>y</td>
<td>numeric matrix of response variables.</td>
</tr>
<tr>
<td>x</td>
<td>numeric covariate vector of length nrow(y), defaults to equally spaced.</td>
</tr>
<tr>
<td>span</td>
<td>width of the smoothing window, in terms of proportion of the data set. Larger values produce smoother curves.</td>
</tr>
<tr>
<td>weights</td>
<td>relative weights of each observation, one for each covariate value.</td>
</tr>
<tr>
<td>degree</td>
<td>degree of local polynomial fit</td>
</tr>
</tbody>
</table>

Details

Fits a loess curve with degree 0 to each column of the response matrix, using the same covariate vector for each column. The smoothed column values are tricube-weighted means of the original values.

locfitByCol uses the locfit.raw function of the locfit package.

Value

A list containing a numeric matrix with smoothed columns and a vector of leverages for each covariate value.

locfitByCol returns a numeric matrix.

Author(s)

Aaron Lun for loessByCol, replacing earlier R code by Davis McCarthy. Gordon Smyth for locfitByCol.

```

---

makeCompressedMatrix   makeCompressedMatrix

Description

Construct a CompressedMatrix object from a scalar, vector or matrix.
Usage

makeCompressedMatrix(x, dims, byrow=TRUE)

## S3 method for class 'CompressedMatrix'
dim(x)
## S3 method for class 'CompressedMatrix'
length(x)

## S3 method for class 'CompressedMatrix'
x[i, j, drop=TRUE]
## S3 replacement method for class 'CompressedMatrix'
x[i, j] <- value

## S3 method for class 'CompressedMatrix'
Ops(e1, e2)

## S3 method for class 'CompressedMatrix'
rbind(...)  
## S3 method for class 'CompressedMatrix'
cbind(...)

## S3 method for class 'CompressedMatrix'
as.matrix(x, ...)

Arguments

x For makeCompressedMatrix, a scalar, vector, matrix or CompressedMatrix object. For the S3 methods, a CompressedMatrix object.
dims an integer vector indicating the matrix dimensions, ignored if x is already a matrix
byrow logical. If x is a vector, should it be repeated across rows (default) or across columns?
i, j subset indices to apply to x, which behave the same as indices for matrix subsetting
drop logical, indicating whether or not to drop dimensions when subsetting to a single row/column
value an array-like object or vector to be used to replace values in x
e1, e2 a CompressedMatrix object
... multiple CompressedMatrix objects for rbind and cbind. Otherwise additional arguments that are ignored in as.matrix.

Details

The CompressedMatrix is used throughout edgeR to save space in storing offsets and (to a lesser extent) weights. This is because, for routine analyses, offsets are the same for all genes so it makes little sense to expand it to the full dimensions of the count matrix. Most functions will accept a CompressedMatrix as input to offset or weights arguments.
**Value**

A object of class `CompressedMatrix`, containing \( x \) and the additional attributes `repeat.row` and `repeat.col`.

**Class construction**

The `makeCompressedMatrix` function creates a `CompressedMatrix` object from \( x \). The `CompressedMatrix` class inherits from a matrix and holds two logical scalar attributes `repeat.row` and `repeat.col`. Each attribute specifies whether the values are to be repeated across rows and/or across columns. This avoids the need to store redundant values in a full-sized matrix of dimensions \( \text{dim} \), as would be done with `expandAsMatrix`.

To illustrate, consider that rows usually correspond to genes while columns usually correspond to libraries. If we have a vector of library sizes, this will hold one unique value per library that is the same for all genes. Thus, we should use `byrow=TRUE`, which will construct a `CompressedMatrix` object storing one row containing this vector. Here, `repeat.row=TRUE` and `repeat.col=FALSE`, indicating that the row is to be repeated for all genes.

On the other hand, we may have a vector of gene-specific values that is the same for all libraries (e.g., dispersions). In this case, we should use `byrow=FALSE` to construct the `CompressedMatrix` object. This will store one column with `repeat.row=FALSE` and `repeat.col=TRUE`, indicating that the column should be repeated across libraries.

In cases where \( x \) is a scalar, `byrow` is ignored and both `repeat.row` and `repeat.col` will be `FALSE` by default. If \( x \) is a matrix, both attributes will be `FALSE`. If \( x \) is a `CompressedMatrix`, it will be returned without modification.

**Class methods**

Subsetting of a `CompressedMatrix` object depends on the values of `repeat.row` and `repeat.col`. If the rows are repeated, any subsetting by row will be effectively ignored, only altering the stored dimensions of \( x \) without changing the values. Similarly, if the columns are repeated, any subsetting by column will be ignored. If neither are repeated, subsetting behaves as it would for a normal matrix.

Combining of a `CompressedMatrix` object will also make use of the repeat structure. If rows are repeated in all objects to be combined, the output of `cbind` will also have repeated rows. Similarly, if columns are repeated, the output of `rbind` will also have repeated columns. Otherwise, all objects are expanded to their full size prior to combining.

Binary operators work on pairs of `CompressedMatrix` objects, again preserving the repeat structure whenever possible. Extracting dimensions uses a second `Dims` field in the attributes, bypassing the `dim` for a base matrix. Calling `as.matrix` on a `CompressedMatrix` object will return the ordinary (uncompressed) matrix.

Examples

# Repeated rows:
library.sizes <- runif(4, 1e6, 2e6)
lib.mat <- makeCompressedMatrix(library.sizes, c(10, 4), byrow=TRUE)
lib.mat
lib.mat[,1:2] # subset by column works as expected
lib.mat[1:10,] # subset by row has no effect (see Details)
as.matrix(lib.mat)

# Repeated columns:
gene.disp <- runif(10, 0.01, 0.1)
disp.mat <- makeCompressedMatrix(gene.disp, c(10, 4), byrow=FALSE)
disp.mat
disp.mat[,1:2] # subset by column has no effect
disp.mat[1:5,] # subset by row works as expected
as.matrix(disp.mat)

# Scalar:
weights <- makeCompressedMatrix(1, c(10, 4))
weights[1:10,] # subsetting has no effect
weights[,1:10]
as.matrix(weights)

# Matrix:
offsets <- makeCompressedMatrix(matrix(runif(40), 10, 4))
offsets[1:5,]
offsets[,1:2]
as.matrix(offsets)

maPlot

Plots Log-Fold Change versus Log-Concentration (or, M versus A) for Count Data

Description

To represent counts that were low (e.g. zero in 1 library and non-zero in the other) in one of the two conditions, a 'smear' of points at low A value is presented.

Usage

maPlot(x, y, logAbundance=NULL, logFC=NULL, normalize=FALSE, plot.it=TRUE,
smearWidth=1, col=NULL, allCol="black", lowCol="orange", deCol="red",
de.tags=NULL, smooth.scatter=FALSE, lowess=FALSE, ...)

Description

To represent counts that were low (e.g. zero in 1 library and non-zero in the other) in one of the two conditions, a 'smear' of points at low A value is presented.

Usage

maPlot(x, y, logAbundance=NULL, logFC=NULL, normalize=FALSE, plot.it=TRUE,
smearWidth=1, col=NULL, allCol="black", lowCol="orange", deCol="red",
de.tags=NULL, smooth.scatter=FALSE, lowess=FALSE, ...)
Arguments

x vector of counts or concentrations (group 1)
y vector of counts or concentrations (group 2)
logAbundance vector providing the abundance of each gene on the log2 scale. Purely optional (default is NULL), but in combination with logFC provides a more direct way to create an MA-plot if the log-abundance and log-fold change are available.
logFC vector providing the log-fold change for each gene for a given experimental contrast. Default is NULL, only to be used together with logAbundance as both need to be non-null for their values to be used.
normalize logical, whether to divide x and y vectors by their sum
plot.it logical, whether to produce a plot
smearWidth scalar, width of the smear
col vector of colours for the points (if NULL, uses allCol and lowCol)
allCol colour of the non-smeared points
lowCol colour of the smeared points
deCol colour of the DE (differentially expressed) points
de.tags indices for genes identified as being differentially expressed; use exactTest or glmLRT to identify DE genes. Note that 'tag' and 'gene' are synonymous here.
smooth.scatter logical, whether to produce a 'smooth scatter' plot using the graphics::smoothScatter function or just a regular scatter plot; default is FALSE, i.e. produce a regular scatter plot
lowess logical, indicating whether or not to add a lowess curve to the MA-plot to give an indication of any trend in the log-fold change with log-concentration
...
... further arguments passed on to plot

Details

The points to be smeared are identified as being equal to the minimum in one of the two groups. The smear is created by using random uniform numbers of width smearWidth to the left of the minimum A value.

Value

a plot to the current device (if plot.it=TRUE), and invisibly returns the M (logFC) and A (logConc) values used for the plot, plus identifiers w and v of genes for which M and A values, or just M values, respectively, were adjusted to make a nicer looking plot.

plotSmear
maximizeInterpolant

Examples

```r
  y <- matrix(rnbinom(10000, mu=5, size=2), ncol=4)
  maPlot(y[,1], y[,2])
```

Description

Maximize a function given a table of values by spline interpolation.

Usage

```r
maximizeInterpolant(x, y)
```

Arguments

- `x`: numeric vector of the inputs of the function.
- `y`: numeric matrix of function values at the values of `x`. Columns correspond to `x` values and each row corresponds to a different function to be maximized.

Details

Calculates the cubic spline interpolant for each row the method of Forsythe et al (1977) using the function `fmm_spline` from `splines.c` in the `stats` package. Then calculates the derivatives of the spline segments adjacent to the input with the maximum function value. This allows identification of the maximum of the interpolating spline.

Value

numeric vector of input values at which the function maximums occur.

Author(s)

Aaron Lun, improving on earlier code by Gordon Smyth

References

Examples

```r
  x <- seq(0,1,length=10)
  y <- rnorm(10,1,1)
  maximizeInterpolant(x,y)
```
Maximize a function given a table of values by quadratic interpolation.

**Description**

Maximize a function given a table of values by quadratic interpolation.

**Usage**

```r
maximizeQuadratic(y, x=1:ncol(y))
```

**Arguments**

- `y` numeric matrix of response values.
- `x` numeric matrix of inputs of the function of same dimension as `y`. If a vector, must be a row vector of length equal to `ncol(y)`.

**Details**

For each row of `y`, finds the three `x` values bracketing the maximum of `y`, interpolates a quadratic polynomial through these `y` for these three values and solves for the location of the maximum of the polynomial.

**Value**

numeric vector of length equal to `nrow(y)` giving the `x`-value at which `y` is maximized.

**Author(s)**

Yunshun Chen and Gordon Smyth

**See Also**

`maximizeInterpolant`

**Examples**

```r
y <- matrix(rnorm(5*9),5,9)
maximizeQuadratic(y)
```
Explore the Mean-Variance Relationship for DGE Data

Description

Appropriate modelling of the mean-variance relationship in DGE data is important for making inferences about differential expression. Here are functions to compute gene means and variances, as well as looking at these quantities when data is binned based on overall expression level.

Usage

plotMeanVar(object, meanvar=NULL, show.raw.vars=FALSE, show.tagwise.vars=FALSE, show.binned.common.disp.vars=FALSE, show.ave.raw.vars=TRUE, scalar=NULL, NBline=FALSE, nbins=100, log.axes="xy", xlab=NULL, ylab=NULL, ...)

binMeanVar(x, group, nbins=100, common.dispersion=FALSE, object=NULL)

Arguments

object DGEList object containing the raw data and dispersion value. According the method desired for computing the dispersion, either estimateCommonDisp and (possibly) estimateTagwiseDisp should be run on the DGEList object before using plotMeanVar. The argument object must be supplied in the function binMeanVar if common dispersion values are to be computed for each bin.

meanvar list (optional) containing the output from binMeanVar or the returned value of plotMeanVar. Providing this object as an argument will save time in computing the gene means and variances when producing a mean-variance plot.

show.raw.vars logical, whether or not to display the raw (pooled) genewise variances on the mean-variance plot. Default is FALSE.

show.tagwise.vars logical, whether or not to display the estimated genewise variances on the mean-variance plot (note that 'tag' and 'gene' are synonymous). Default is FALSE.

show.binned.common.disp.vars logical, whether or not to compute the common dispersion for each bin of genes and show the variances computed from those binned common dispersions and the mean expression level of the respective bin of genes. Default is FALSE.

show.ave.raw.vars logical, whether or not to show the average of the raw variances for each bin of genes plotted against the average expression level of the genes in the bin. Averages are taken on the square root scale as regular arithmetic means are likely to be upwardly biased for count data, whereas averaging on the square scale gives a better summary of the mean-variance relationship in the data. The default is TRUE.

scalar vector (optional) of scaling values to divide counts by. Would expect to have this the same length as the number of columns in the count matrix (i.e. the number of libraries).
meanvar

NBlime logical, whether or not to add a line on the graph showing the mean-variance relationship for a NB model with common dispersion.

nbins scalar giving the number of bins (formed by using the quantiles of the genewise mean expression levels) for which to compute average means and variances for exploring the mean-variance relationship. Default is 100 bins.

log.axes character vector indicating if any of the axes should use a log scale. Default is "xy", which makes both y and x axes on the log scale. Other valid options are "x" (log scale on x-axis only), "y" (log scale on y-axis only) and "" (linear scale on x- and y-axis).

xlab character string giving the label for the x-axis. Standard graphical parameter. If left as the default NULL, then the x-axis label will be set to "logConc".

ylab character string giving the label for the y-axis. Standard graphical parameter. If left as the default NULL, then the x-axis label will be set to "logConc".

... further arguments passed on to plot

x matrix of count data, with rows representing genes and columns representing samples

group factor giving the experimental group or condition to which each sample (i.e. column of x or element of y) belongs

common.dispersion logical, whether or not to compute the common dispersion for each bin of genes.

Details

This function is useful for exploring the mean-variance relationship in the data. Raw variances are, for each gene, the pooled variance of the counts from each sample, divided by a scaling factor (by default the effective library size). The function will plot the average raw variance for genes split into nbins bins by overall expression level. The averages are taken on the square-root scale as for count data the arithmetic mean is upwardly biased. Taking averages on the square-root scale provides a useful summary of how the variance of the gene counts change with respect to expression level (abundance). A line showing the Poisson mean-variance relationship (mean equals variance) is always shown to illustrate how the genewise variances may differ from a Poisson mean-variance relationship. Optionally, the raw variances and estimated genewise variances can also be plotted. Estimated genewise variances can be calculated using either qCML estimates of the genewise dispersions (estimateTagwiseDisp) or Cox-Reid conditional inference estimates (CRDisp). A log-log scale is used for the plot.

Value

plotMeanVar produces a mean-variance plot for the DGE data using the options described above. plotMeanVar and binMeanVar both return a list with the following components:

avemean vector of the average expression level within each bin of genes, with the average taken on the square-root scale

avevars vector of the average raw pooled gene-wise variance within each bin of genes, with the average taken on the square-root scale

bin.means list containing the average (mean) expression level for genes divided into bins based on amount of expression
bin.vars  list containing the pooled variance for genes divided into bins based on amount of expression
means   vector giving the mean expression level for each gene
vars    vector giving the pooled variance for each gene
bins    list giving the indices of the genes in each bin, ordered from lowest expression bin to highest

Author(s)
Davis McCarthy

See Also
plotMeanVar2 is related in purpose but works from raw counts and uses standardized residuals. plotMDS.DGEList, plotSmear and maPlot provide more ways of visualizing DGE data.

Examples

```r
y <- matrix(rnbinom(1000, mu=10, size=2), ncol=4)
d <- DGEList(counts=y, group=c(1,1,2,2), lib.size=c(1000:1003))
plotMeanVar(d) # Produce a straight-forward mean-variance plot
# Produce a mean-variance plot with the raw variances shown and save the means
# and variances for later use
meanvar <- plotMeanVar(d, show.raw.vars=TRUE)
## If we want to show estimated genewise variances on the plot, we must first estimate them!
d <- estimateCommonDisp(d) # Obtain an estimate of the dispersion parameter
d <- estimateTagwiseDisp(d) # Obtain genewise dispersion estimates
# Use previously saved object to speed up plotting
plotMeanVar(d, meanvar=meanvar, show.tagwise.vars=TRUE, NBline=TRUE)
## We could also estimate common/genewise dispersions using the Cox-Reid methods with an
## appropriate design matrix
```

**mglm**

*Fit Negative Binomial Generalized Linear Models to Multiple Response Vectors: Low Level Functions*

**Description**

Fit the same log-link negative binomial or Poisson generalized linear model (GLM) to each row of a matrix of counts.

**Usage**

```r
mglmOneGroup(y, dispersion = 0, offset = 0, weights = NULL,
             coef.start = NULL, maxit = 50, tol = 1e-10, verbose = FALSE)
mglmOneWay(y, design = NULL, group = NULL, dispersion = 0, offset = 0, weights = NULL,
            coef.start = NULL, maxit = 50, tol = 1e-10)
```
mglmLevenberg(y, design, dispersion = 0, offset = 0, weights = NULL, 
    coef.start = NULL, start.method = "null", maxit = 200, tol = 1e-06) 
    designAsFactor(design)

**Arguments**

- **y**: numeric matrix containing the negative binomial counts. Rows for genes and columns for libraries.
- **design**: numeric matrix giving the design matrix of the GLM. Assumed to be full column rank. This is a required argument for mglmLevenberg and code(designAsFactor). For mglmOneWay, it defaults to model.matrix(~0+group) if group is specified and otherwise to model.matrix(~1).
- **group**: factor giving group membership for oneway layout. If both design and group are both specified, then they must agree in terms of designAsFactor. If design=NULL, then a group-means design matrix is implied.
- **dispersion**: numeric scalar or vector giving the dispersion parameter for each GLM. Can be a scalar giving one value for all genes, or a vector of length equal to the number of genes giving genewise dispersions.
- **offset**: numeric vector or matrix giving the offset that is to be included in the log-linear model predictor. Can be a scalar, a vector of length equal to the number of libraries, or a matrix of the same size as `y`.
- **weights**: numeric vector or matrix of non-negative quantitative weights. Can be a vector of length equal to the number of libraries, or a matrix of the same size as `y`.
- **coef.start**: numeric matrix of starting values for the linear model coefficients. Number of rows should agree with `y` and number of columns should agree with `design`. For mglmOneGroup, a numeric vector or a matrix with one column. This argument does not usually need to be set as the automatic starting values perform well.
- **start.method**: method used to generate starting values when `coef.stat=NULL`. Possible values are "null" to start from the null model of equal expression levels or "y" to use the data as starting value for the mean.
- **tol**: numeric scalar giving the convergence tolerance. For mglmOneGroup, convergence is judged successful when the step size falls below `tol` in absolute size.
- **maxit**: integer giving the maximum number of iterations for the Fisher scoring algorithm. The iteration will be stopped when this limit is reached even if the convergence criterion hasn’t been satisfied.
- **verbose**: logical. If TRUE, warnings will be issued when maxit iterations are exceeded before convergence is achieved.

**Details**

These functions are low-level work-horses used by higher-level functions in the edgeR package, especially by glmFit. Most users will not need to call these functions directly.

The functions mglmOneGroup, mglmOneWay and mglmLevenberg all fit a negative binomial GLM to each row of `y`. The row-wise GLMs all have the same design matrix but possibly different dispersions, offsets and weights. These functions are all low-level in that they operate on atomic objects (numeric matrices and vectors).
mglm

mglmOneGroup fits an intercept only model to each response vector. In other words, it treats all the libraries as belonging to one group. It implements Fisher scoring with a score-statistic stopping criterion for each gene. Excellent starting values are available for the null model so this function seldom has any problems with convergence. It is used by other edgeR functions to compute the overall abundance for each gene.

mglmOneWay fits a oneway layout to each response vector. It treats the libraries as belonging to a number of groups and calls mglmOneGroup for each group.

mglmLevenberg fits an arbitrary log-linear model to each response vector. It implements a Levenberg-Marquardt modification of the GLM scoring algorithm to prevent divergence. The main computation is implemented in C++.

All these functions treat the dispersion parameter of the negative binomial distribution as a known input.

designAsFactor is used to convert a general design matrix into a oneway layout if that is possible. It determines how many distinct row values the design matrix is capable of computing and returns a factor with a level for each possible distinct value.

Value

mglmOneGroup produces a numeric vector of coefficients.

mglmOneWay produces a list with the following components:

coefficients matrix of estimated coefficients for the linear models. Rows correspond to rows of y and columns to columns of design.

fitted.values matrix of fitted values. Of same dimensions as y.

mglmLevenberg produces a list with the following components:

coefficients matrix of estimated coefficients for the linear models.

fitted.values matrix of fitted values.

deviance numeric vector of residual deviances.

iter number of iterations used.

fail logical vector indicating genes for which the maximum damping was exceeded before convergence was achieved.

designAsFactor returns a factor of length equal to nrow(design).

See Also

Most users will call either `glmFit`, the higher-level function offering more object-orientated GLM modelling of DGE data, or else `exactTest`, which is designed for oneway layouts.

Examples

```r
y <- matrix(rnbinom(1000, mu = 10, size = 2), ncol = 4)
lib.size <- colSums(y)
dispersion <- 0.1

## Compute intercept for each row
beta <- mglmOneGroup(y, dispersion = dispersion, offset = log(lib.size))

## Unlogged intercepts add to one:
sum(exp(beta))

## Fit the NB GLM to the counts with a given design matrix
f1 <- factor(c(1,1,2,2))
f2 <- factor(c(1,2,1,2))
X <- model.matrix(~ f1 + f2)
fit <- mglmLevenberg(y, X, dispersion = dispersion, offset = log(lib.size))
head(fit$coefficients)
```

---

### modelMatrixMeth

**Construct Design Matrix for edgeR Analysis of Methylation Count Data**

**Description**

Construct design matrix (aka model matrix) for edgeR analysis of methylation count data from sample level information.

**Usage**

```r
modelMatrixMeth(object, ...)
```

**Arguments**

- `object`: a sample-level design matrix or model formula or terms object.
- `...`: any other arguments are passed to `model.matrix`.

**Details**

This function computes a design matrix for modeling methylated and unmethylated counts. The resulting design matrix can be input to `glmFit` when analysing BS-seq methylation data using edgeR.

In BS-seq methylation analysis, each DNA sample generates two counts, a count of methylated reads and a count of unmethylated reads, for each genomic locus for each sample. The function
converts sample-level information about the treatment conditions to make an appropriate design matrix with two rows for each sample. Counts are assumed to be ordered as methylated and then unmethylated by sample.

If `design.treatments <- model.matrix(object,...)` has `nsamples` rows and `p` columns, then `modelMatrixMeth(object, ...)` has `2*nsamples` rows and `nsamples+p` columns. See Chen et al (2017) for more information.

Value

A numeric design matrix. It has 2 rows for each sample and a column for each sample in addition to the columns generated by `model.matrix(object, ...)`. 

Author(s)

Gordon Smyth

References

See Also

`model.matrix` in the stats package.

Examples

```r
Treatments <- gl(3,2,labels=c("A","B","C"))
modelMatrixMeth(~Treatments)

# Equivalent calling sequence:
design.treatments <- model.matrix(~Treatments)
modelMatrixMeth(design.treatments)
```

---

**movingAverageByCol**  
*Moving Average Smoother of Matrix Columns*

Description

Apply a moving average smoother to the columns of a matrix.

Usage

```r
movingAverageByCol(x, width=5, full.length=TRUE)
```
Arguments

- **x**: numeric matrix
- **width**: integer, width of window of rows to be averaged
- **full.length**: logical value, should output have same number of rows as input?

Details

If `full.length=TRUE`, narrower windows are used at the start and end of each column to make a column of the same length as input. If `FALSE`, all values are averager of `width` input values, so the number of rows is less than input.

Value

Numeric matrix containing smoothed values. If `full.length=TRUE`, of same dimension as `x`. If `full.length=FALSE`, has `width-1` fewer rows than `x`.

Author(s)

Gordon Smyth

Examples

```r
x <- matrix(rpois(20,lambda=5),10,2)
movingAverageByCol(x,3)
```

---

**nbinomDeviance**

Negative Binomial Deviance

Description

Fit the same log-link negative binomial or Poisson generalized linear model (GLM) to each row of a matrix of counts.

Usage

```
nbinomDeviance(y, mean, dispersion=0, weights=NULL)
```

Arguments

- **y**: numeric matrix containing the negative binomial counts, with rows for genes and columns for libraries. A vector will be treated as a matrix with one row.
- **mean**: numeric matrix of expected values, of same dimension as `y`. A vector will be treated as a matrix with one row.
- **dispersion**: numeric vector or matrix of negative binomial dispersions, as for `glmFit`. Can be a scalar, a vector of length equal to `nrow(y)`, or a matrix of same dimensions as `y`.

Usage

```
nbinomDeviance(y, mean, dispersion=0, weights=NULL)
```

Arguments

- **y**: numeric matrix containing the negative binomial counts, with rows for genes and columns for libraries. A vector will be treated as a matrix with one row.
- **mean**: numeric matrix of expected values, of same dimension as `y`. A vector will be treated as a matrix with one row.
- **dispersion**: numeric vector or matrix of negative binomial dispersions, as for `glmFit`. Can be a scalar, a vector of length equal to `nrow(y)`, or a matrix of same dimensions as `y`.
weights numeric vector or matrix of non-negative weights, as for `glmFit`. Can be a scalar, a vector of length equal to `ncol(y)`, or a matrix of same dimensions as `y`.

Details

Computes the total residual deviance for each row of `y`, i.e., weighted row sums of the unit deviances.

Care is taken to ensure accurate computation in limiting cases when the dispersion is near zero or `mean*dispersion` is very large.

Value

`nbinomDeviance` returns a numeric vector of length equal to the number of rows of `y`.

Author(s)

References

See Also

`nbinomUnitDeviance`

Examples

```r
y <- matrix(1:6,3,2)
mu <- matrix(3,3,2)
nbinomDeviance(y,mu,dispersion=0.2)
```
nbinomUnitDeviance  

Negative Binomial Unit Deviance

Description

Compute unit deviances for the negative binomial distribution.

Usage

nbinomUnitDeviance(y, mean, dispersion = 0)

Arguments

y  
numeric vector or matrix containing negative binomial counts.

mean  
numeric vector or matrix of expected values. If a matrix, then of same dimensions as y.

dispersion  
numeric vector or matrix of negative binomial dispersions. Can be a scalar, a vector of length nrow(y) or a matrix of same dimensions as y.

Details

The unit deviance of the negative binomial distribution is a measure of the distance between y and mean. If mean and dispersion are the true mean and dispersion of the negative binomial distribution, then the unit deviance follows an approximate chisquare distribution on 1 degree of freedom.

This function computes the unit deviance for each y observation. Care is taken to ensure accurate computation in limiting cases when the dispersion is near zero or mean*dispersion is very large.

Value

Numeric vector or matrix of the same size as y containing unit deviances.

Author(s)

References

Examples

```r
y <- 1:4
names(y) <- letters[1:4]
nbinomUnitDeviance(y, mean=2.5, dispersion=0.2)
```

nearestReftoX

Find Nearest Element of Reference for each Element of X

Description

Find nearest element of a sorted reference vector and to each element of x.

Usage

```r
nearestReftoX(x, reference, ...)
```

Arguments

- `x`: numeric vector.
- `reference`: numeric vector, sorted in increasing order.
- `...`: other arguments as passed to `findInterval`.

Details

This function finds the element of a reference table (`reference`) that is closest to each element of an incoming vector (`x`).

The function is a simple wrapper for `findInterval` in the base package. It calls `findInterval` with `vec` equal to the mid-points between the reference values.

Value

Integer vector giving indices of elements of `reference`.

Author(s)

Gordon Smyth

See Also

`findInterval`

Examples

```r
nearestReftoX(c(-10,0.5,0.6,2,3), reference = c(-1,0,2))
```
nearestTSS

Find Nearest Transcriptional Start Site

Description

Find nearest TSS and distance to nearest TSS for a vector of chromosome loci.

Usage

nearestTSS(chr, locus, species="Hs")

Arguments

chr character vector of chromosome names.
locus integer or numeric vector of genomic loci, of same length as chr.
species character string specifying the species. Possible values are "Hs" (human hg38), "Mm" (mouse mm10), "Rn" (rat), "Dm" (fly), "Dr" (zebra fish), "Ce" (worm), "Bt" (bovine), "Gg" (chicken), "Mmu" (rhesus), "Cf" (canine) or "Pt" (chimpanzee).

Details

This function takes a series of genomic loci, defined by a vector of chromosome names and a vector of genomic positions within the chromosomes, and finds the nearest transcriptional start site (TSS) for each locus. The chromosome names can be in the format "1", "2", "X" or can be "chr1", "chr2", "chrX".

For genes with more than one annotated TSS, only the most 5' (upstream) of the alternative TSS is reported.

This function uses the Bioconductor organism package named "org.XX.eg.db" where XX is species. Note that each organism package supports only a particular build of the genome for that species. For human (species="Hs"), the results are for the hg38 genome build. For mouse (species="Mm"), the results are for the mm10 genome build.

Value

A data.frame with the following columns:

gene_id character vector giving the Entrez Gene ID of the nearest TSS for each element of chr and locus.
symbol character vector of gene symbols.
strand character vector with "+" for positive strand genes and "-" for negative strand genes.
tss integer vector giving TSS.
width integer vector giving genomic width of the gene.
distance integer vector giving distance to nearest TSS. Positive values means that the TSS is downstream of the locus, negative values means that it is upstream. Gene body loci will therefore have negative distances and promotor loci will have positive.
normalizeChIPtoInput

Author(s)
Gordon Smyth

See Also
nearestReftoX

Examples

nearestTSS(chr = c("1","1"), locus = c(1000000,2000000))

normalizeChIPtoInput Normalize ChIP-Seq Read Counts to Input and Test for Enrichment

Description
Normalize ChIP-Seq read counts to input control values, then test for significant enrichment relative to the control.

Usage

normalizeChIPtoInput(input, response, dispersion=0.01, niter=6, loss="p", plot=FALSE, verbose=FALSE, ...)
calcNormOffsetsforChIP(input, response, dispersion=0.01, niter=6, loss="p", plot=FALSE, verbose=FALSE, ...)

Arguments

input numeric vector of non-negative input values, not necessarily integer.
response vector of non-negative integer counts of some ChIP-Seq mark for each gene or other genomic feature.
dispersion negative binomial dispersion, must be positive.
niter number of iterations.
loss loss function to be used when fitting the response counts to the input: "p" for cumulative probabilities or "z" for z-value.
plot if TRUE, a plot of the fit is produced.
verbose if TRUE, working estimates from each iteration are output.
... other arguments are passed to the plot function.
Details

normalizeChIPtoInput identifies significant enrichment for a ChIP-Seq mark relative to input values. The ChIP-Seq mark might be for example transcriptional factor binding or an epigenetic mark. The function works on the data from one sample. Replicate libraries are not explicitly accounted for; this function can either be run on each sample individually or on a pooled of replicates.

ChIP-Seq counts are assumed to be summarized by gene or similar genomic feature of interest.

This function makes the assumption that a non-negligible proportion of the genes, say 25% or more, are not truly marked by the ChIP-Seq feature of interest. Unmarked genes are further assumed to have counts at a background level proportional to the input. The function aligns the counts to the input so that the counts for the unmarked genes behave like a random sample. The function estimates the proportion of marked genes, and removes marked genes from the fitting process. For this purpose, marked genes are those with a Holm-adjusted mid-p-value less than 0.5.

When plot=TRUE, the genes shown in red are the marked genes (with Holm mid-p-value < 0.5) that have been removed as probably enriched during the fitting process. The normalization line has been fitted to the non-marked genes plotted in black.

The read counts are treated as negative binomial. The dispersion parameter is not estimated from the data; instead a reasonable value is assumed to be given.

calcNormOffsetsforChIP returns a numeric matrix of offsets, ready for linear modelling.

Value

normalizeChIPtoInput returns a list with components

- p.value numeric vector of p-values for enrichment.
- scaling.factor factor by which input is scaled to align with response counts for unmarked genes.
- prop.enriched proportion of marked genes, as internally estimated

calcNormOffsetsforChIP returns a numeric matrix of offsets.

Author(s)

Gordon Smyth

---

normLibSizes Normalize Library Sizes

Description

Calculate scaling factors to convert the raw library sizes for a set of sequenced samples into normalized effective library sizes.
Usage

```r
## S3 method for class 'DGEList'
normLibSizes(object,
             method = c("TMM", "TMMwsp", "RLE", "upperquartile", "none"),
             refColumn = NULL, logratioTrim = .3, sumTrim = 0.05, doWeighting = TRUE,
             A cutoff = -1e10, p = 0.75, ...)
## S3 method for class 'SummarizedExperiment'
normLibSizes(object,
             method = c("TMM", "TMMwsp", "RLE", "upperquartile", "none"),
             refColumn = NULL, logratioTrim = .3, sumTrim = 0.05, doWeighting = TRUE,
             A cutoff = -1e10, p = 0.75, ...)
## Default S3 method:
normLibSizes(object, lib.size = NULL,
             method = c("TMM", "TMMwsp", "RLE", "upperquartile", "none"),
             refColumn = NULL, logratioTrim = .3, sumTrim = 0.05, doWeighting = TRUE,
             A cutoff = -1e10, p = 0.75, ...)
## S3 method for class 'DGEList'
calcNormFactors(object,
                method = c("TMM", "TMMwsp", "RLE", "upperquartile", "none"),
                refColumn = NULL, logratioTrim = .3, sumTrim = 0.05, doWeighting = TRUE,
                A cutoff = -1e10, p = 0.75, ...)
## S3 method for class 'SummarizedExperiment'
calcNormFactors(object,
                method = c("TMM", "TMMwsp", "RLE", "upperquartile", "none"),
                refColumn = NULL, logratioTrim = .3, sumTrim = 0.05, doWeighting = TRUE,
                A cutoff = -1e10, p = 0.75, ...)
## Default S3 method:
calcNormFactors(object, lib.size = NULL,
                method = c("TMM", "TMMwsp", "RLE", "upperquartile", "none"),
                refColumn = NULL, logratioTrim = .3, sumTrim = 0.05, doWeighting = TRUE,
                A cutoff = -1e10, p = 0.75, ...)
```

Arguments

- **object**: a matrix of raw read counts or a DGEList object or a SummarizedExperiment object.
- **lib.size**: numeric vector of library sizes corresponding to the columns of the matrix object.
- **method**: normalization method to be used.
- **refColumn**: column to use as reference for method="TMM". Can be a column number or a numeric vector of length nrow(object).
- **logratioTrim**: the fraction (0 to 0.5) of observations to be trimmed from each tail of the distribution of log-ratios (M-values) before computing the mean. Used by method="TMM" for each pair of samples.
- **sumTrim**: the fraction (0 to 0.5) of observations to be trimmed from each tail of the distribution of A-values before computing the mean. Used by method="TMM" for each pair of samples.
each pair of samples.

doWeighting logical, whether to use (asymptotic binomial precision) weights when computing the mean M-values. Used by method="TMM" for each pair of samples.

Acutoff minimum cutoff applied to A-values. Count pairs with lower A-values are ignored. Used by method="TMM" for each pair of samples.

p numeric value between 0 and 1 specifying which quantile of the counts should be used by method="upperquartile".

... other arguments are not currently used.

Details

This function computes scaling factors to convert observed library sizes into normalized library sizes, also called "effective library sizes". The effective library sizes for use in downstream analysis are \( \text{lib.size} \times \text{norm.factors} \) where \( \text{lib.size} \) contains the original library sizes and \( \text{norm.factors} \) is the vector of scaling factors computed by this function.

The TMM method implements the trimmed mean of M-values method proposed by Robinson and Oshlack (2010). By default, the M-values are weighted according to inverse variances, as computed by the delta method for logarithms of binomial random variables. If \( \text{refColumn} \) is unspecified, then the column whose count-per-million upper quartile is closest to the mean upper quartile is set as the reference library.

The TMMwsp method stands for "TMM with singleton pairing". This is a variant of TMM that is intended to have more stable performance when the counts have a high proportion of zeros. In the TMM method, genes that have zero count in either library are ignored when comparing pairs of libraries. In the TMMwsp method, the positive counts from such genes are reused to increase the number of features by which the libraries are compared. The singleton positive counts are paired up between the libraries in decreasing order of size and then a slightly modified TMM method is applied to the re-ordered libraries. If \( \text{refColumn} \) is unspecified, then the column with largest sum of square-root counts is used as the reference library.

RLE is the scaling factor method proposed by Anders and Huber (2010). We call it "relative log expression", as median library is calculated from the geometric mean of all columns and the median ratio of each sample to the median library is taken as the scale factor.

The upperquartile method is the upper-quartile normalization method of Bullard et al (2010), in which the scale factors are calculated from the 75\% quantile of the counts for each library, after removing genes that are zero in all libraries. The idea is generalized here to allow normalization by any quantile of the count distributions.

If method="none", then the normalization factors are set to 1.

For symmetry, normalization factors are adjusted to multiply to 1. Rows of object that have zero counts for all columns are removed before normalization factors are computed. The number of such rows does not affect the estimated normalization factors.

If object is a SummarizedExperiment object, then it is converted to a DGEList using SE2DGEList and the DGEList method applied.

Value

If object is a matrix, then the output is a vector with length ncol(object) giving the library scaling factors.
If `object` is a `DGEList` or `SummarizedExperiment` object, then the output is a `DGEList` the same as input with the library scaling factors stored as `object$samples$norm.factors`.

**Note**

`normLibSizes` is the new name for `calcNormFactors`. The two functions are equivalent but `calcNormFactors` will eventually be retired.

**Author(s)**

Mark Robinson, Gordon Smyth, Yunshun Chen.

**References**

**See Also**

`getNormLibSizes`, `SE2DGEList`.

**Examples**

```r
y <- matrix( rpois(1000, lambda=5), nrow=200 )
normLibSizes(y)

# The TMM and TMMwsp methods give zero weight to the genes with the largest fold-changes:
y <- cbind(1,c(1,1,1,1,1,1,1,1,1,1,100))
normLibSizes(y, lib.size=c(1e6,1e6))

# normLibSizes makes the fold-changes for the majority of genes as close to 1 as possible:
# In this example, computing CPMs with raw library sizes makes the two samples look quite different.
dge <- DGEList(counts=y)
cpm(dge)
# By contrast, normalizing the library sizes makes most of the CPMs equal in the two samples:
dge <- normLibSizes(dge)
cpm(dge)
getNormLibSizes(dge)
```
Description

Plot the genewise biological coefficient of variation (BCV) against gene abundance (in log2 counts per million).

Usage

plotBCV(y, xlab="Average log CPM", ylab="Biological coefficient of variation", pch=16, cex=0.2, col.common="red", col.trend="blue", col.tagwise="black", ...)

Arguments

- **y**: a DGEList object.
- **xlab**: label for the x-axis.
- **ylab**: label for the y-axis.
- **pch**: the plotting symbol. See points for more details.
- **cex**: plot symbol expansion factor. See points for more details.
- **col.common**: color of line showing common dispersion
- **col.trend**: color of line showing dispersion trend
- **col.tagwise**: color of points showing genewise dispersions. Note that ‘tag’ and ‘gene’ are synonymous here.
- ... any other arguments are passed to plot.

Details

The BCV is the square root of the negative binomial dispersion. This function displays the common, trended and genewise BCV estimates.

Value

A plot is created on the current graphics device.

Author(s)

Davis McCarthy, Yunshun Chen, Gordon Smyth

Examples

```r
BCV.true <- 0.1
y <- DGEList(matrix(rnbinom(6000, size = 1/BCV.true^2, mu = 10),1000,6))
y <- estimateCommonDisp(y)
y <- estimateTrendedDisp(y)
y <- estimateTagwiseDisp(y)
plotBCV(y)
```
plotExonUsage  Create a Plot of Exon Usage from Exon-Level Count Data

Description

Create a plot of exon usage for a given gene by plotting the (un)transformed counts for each exon, coloured by experimental group.

Usage

plotExonUsage(y, geneID, group=NULL, transform="none", counts.per.million=TRUE, legend.coords=NULL, ...)

Arguments

y  either a matrix of exon-level counts, a list containing a matrix of counts for each exon or a DGEList object with (at least) elements counts (table of counts summarized at the exon level) and samples (data frame containing information about experimental group, library size and normalization factor for the library size). Each row of y should represent one exon.

geneID  character string giving the name of the gene for which exon usage is to be plotted.

group  factor supplying the experimental group/condition to which each sample (column of y) belongs. If NULL (default) the function will try to extract if from y, which only works if y is a DGEList object.

transform  character, supplying the method of transformation to be applied to the exon counts, if any. Options are "none" (original counts are preserved), "sqrt" (square-root transformation) and "log2" (log2 transformation). Default is "none".

counts.per.million  logical, if TRUE then counts per million (as determined from total library sizes) will be plotted for each exon, if FALSE the raw read counts will be plotted. Using counts per million effectively normalizes for different read depth among the different samples, which can make the exon usage plots easier to interpret.

legend.coords  optional vector of length 2 giving the x- and y-coordinates of the legend on the plot. If NULL (default), the legend will be automatically placed near the top right corner of the plot.

...  optional further arguments to be passed on to plot.

Details

This function produces a simple plot for comparing exon usage between different experimental conditions for a given gene.

Value

plotExonUsage (invisibly) returns the transformed matrix of counts for the gene being plotted and produces a plot to the current device.
plotMD.DGEList

d<-DGEList(counts=y, group=rep(1:2, each=2))
plotExonUsage(d, "gene.1")

plotMD.DGEList Mean-Difference Plot of Count Data

Description

Creates a mean-difference plot (aka MA plot) with color coding for highlighted points.

Usage

## S3 method for class 'DGEList'
plotMD(object, column=1, xlab="Average log CPM (this sample and others)", ylab="log-ratio (this sample vs others)", main=colnames(object)[column], status=object$genes>Status, zero.weights=FALSE, prior.count=3, ...)
## S3 method for class 'SummarizedExperiment'
plotMD(object, column=1, xlab="Average log CPM (this sample and others)", ylab="log-ratio (this sample vs others)", zero.weights=FALSE, prior.count=3, ...)
## S3 method for class 'DGEGLM'
plotMD(object, column=ncol(object), coef=NULL, xlab="Average log CPM", ylab="log-fold-change", main=colnames(object)[column], status=object$genes>Status, zero.weights=FALSE, ...)
## S3 method for class 'DGELRT'
plotMD(object, xlab="Average log CPM", ylab="log-fold-change", main=object$comparison, status=object$genes>Status, contrast=1, adjust.method="BH", p.value=0.05, ...)
## S3 method for class 'DGEExact'
plotMD(object, xlab="Average log CPM", ylab="log-fold-change", main=NULL, status=object$genes>Status, adjust.method="BH", p.value=0.05, ...)
Arguments

object  an object of class DGEList, SummarizedExperiment, DGEGLM, DGEGLM or DGEEexact.
column  integer, column of object to be plotted.
coef    alternative to column for fitted model objects. If specified, then column is ignored.
xlab    character string, label for x-axis
ylab    character string, label for y-axis
main    character string, title for plot
status  vector giving the control status of each spot on the array, of same length as the number of rows of object. If NULL under the DGEList, SummarizedExperiment or DGEGLM method, then all points are plotted in the default color, symbol and size. If NULL under the DGELRT or DGEEexact method, then decideTestsDGE is run to determine the status of all the genes. The up-regulated DE genes are highlighted in red and down-regulated in blue.
zero.weights logical, should spots with zero or negative weights be plotted?
prior.count the average prior count to be added to each observation. Larger values produce more shrinkage.
contrast integer specifying which log-fold-change to be plotted in the case of testing multiple contrasts. Only used for the DGELRT method with multiple contrasts.
adjust.method character string passed to decideTestsDGE specifying p-value adjustment method. Only used when status is NULL. See decideTestsDGE for details.
p.value numeric value between 0 and 1 giving the desired size of the test. Only used and passed to decideTestsDGE when status is NULL.
...    other arguments are passed to plotWithHighlights.

Details

A mean-difference plot (MD-plot) is a plot of log fold changes (differences) versus average log values (means). The history of mean-difference plots and MA-plots is reviewed in Ritchie et al (2015).

For DGEList and SummarizedExperiment objects, a between-sample MD-plot is produced. Counts are first converted to log2-CPM values. An artifical array is produced by averaging all the samples other than the sample specified. A mean-difference plot is then producing from the specified sample and the artificial sample. This procedure reduces to an ordinary mean-difference plot when there are just two arrays total.

If object is an DGEGLM object, then the plot is an fitted model MD-plot in which the estimated coefficient is on the y-axis and the average logCPM value is on the x-axis. If object is an DGEEexact or DGELRT object, then the MD-plot displays the logFC vs the logCPM values from the results table.

The status vector can correspond to any grouping of the probes that is of interest. If object is a fitted model object, then status vector is often used to indicate statistically significance, so that differentially expressed points are highlighted.

The status can be included as the component object$genes$Status instead of being passed as an argument to plotMD.

See plotWithHighlights for how to set colors and graphics parameters for the highlighted and non-highlighted points.
plotMDS.DGEList

Value
A plot is created on the current graphics device.

Author(s)
Gordon Smyth

References

The driver function for plotMD is plotWithHighlights.

---

plotMDS.DGEList | *Multidimensional scaling plot of distances between digital gene expression profiles*

---

Description
Plot samples on a two-dimensional scatterplot so that distances on the plot approximate the expression differences between the samples.

Usage
```
## S3 method for class 'DGEList'
plotMDS(x, top = 500, labels = NULL, pch = NULL, cex = 1,
dim.plot = c(1,2), gene.selection = "pairwise", xlab = NULL, ylab = NULL,
method = "logFC", prior.count = 2, plot = TRUE, var.explained = TRUE, ...)
```

Arguments
- `x`: a DGEList or SummarizedExperiment object.
- `top`: number of top genes used to calculate pairwise distances.
- `labels`: character vector of sample names or labels. If `x` has no column names, then defaults the index of the samples.
- `pch`: plotting symbol or symbols. See `points` for possible values. Ignored if `labels` is non-NULL.
- `cex`: numeric vector of plot symbol expansions. See `text` for possible values.
- `dim.plot`: which two dimensions should be plotted, numeric vector of length two.
gene.selection character, "pairwise" to choose the top genes separately for each pairwise comparison between the samples, or "common" to select the same genes for all comparisons. Only used when method="logFC".

xlab x-axis label

ylab y-axis label

method method used to compute distances. Possible values are "logFC" or "bcv". Note the "bcv" method is scheduled to be removed in a future version of edgeR.

prior.count average prior count to be added to observation to shrink the estimated log-fold-changes towards zero. Only used when method="logFC".

plot logical. If TRUE then a plot is created on the current graphics device.

var.explained logical. If TRUE then the percentage variation explained is included in the axis labels.

... any other arguments are passed to plot.

Details

The default method (method="logFC") is to convert the counts to log-counts-per-million using cpm and to pass these to the limma plotMDS function. This method calculates distances between samples based on log2 fold changes. See the plotMDS help page for details.

The alternative method (method="bcv") calculates distances based on biological coefficient of variation. A set of top genes are chosen that have largest biological variation between the libraries (those with largest genewise dispersion treating all libraries as one group). Then the distance between each pair of libraries (columns) is the biological coefficient of variation (square root of the common dispersion) between those two libraries alone, using the top genes. Beware that the "bcv" method is slow when the number of samples is large. The "bcv" method is in general much less used than "logFC" and is scheduled to be removed in a future version of edgeR.

The number of genes (top) chosen for this exercise should roughly correspond to the number of differentially expressed genes with materially large fold-changes. The default setting of 500 genes is widely effective and suitable for routine use, but a smaller value might be chosen for when the samples are distinguished by a specific focused molecular pathway. Very large values (greater than 1000) are not usually so effective.

Value

An object of class MDS is invisibly returned and (if plot=TRUE) a plot is created on the current graphics device.

# or labels can be provided, here group indicators:
plotMDS(mds, col=col, labels=group)

plotMeanVar2

Plot Mean-Variance Relationship in DGE Data Using Standardized Residuals

Description

Group observations by size of the fitted value and plot average squared residual vs average fitted value.

Usage

plotMeanVar2(y, design = NULL, dispersion = 0, offset = 0, nbins = 100, make.plot = TRUE,
xlab = “Mean”, ylab = “Ave. binned standardized residual”, …)

Arguments

y numeric matrix of counts, each row represents one genes, each column represents one DGE library.
design numeric matrix giving the design matrix of the GLM. Assumed to be full column rank. Defaults to a intercept column.
dispersion numeric scalar or vector giving the dispersion parameter for each GLM. Can be a scalar giving one value for all genes, or a vector of length equal to the number of genes giving genewise dispersions.
offset numeric vector or matrix giving the offset that is to be included in teh log-linear model predictor. Can be a vector of length equal to the number of libraries, or a matrix of the same size as y.
nbins scalar giving the number of bins (formed by using the quantiles of the genewise mean expression levels) for which to compute average means and variances for exploring the mean-variance relationship. Default is 100 bins

make.plot logical, whether or not to plot the mean standardized residual for binned data (binned on expression level). Provides a visualization of the mean-variance relationship. Default is TRUE.

xlab character string giving the label for the x-axis. Standard graphical parameter. If left as the default, then the x-axis label will be set to "Mean".

ylab character string giving the label for the y-axis. Standard graphical parameter. If left as the default, then the y-axis label will be set to "Ave. binned standardized residual".

... other arguments are passed to plot

Details

This function explores the mean-variance relationship in count data. The function fits a Poisson or NB GLM model to each gene using the appropriate design matrix and computes squared ordinary residuals. The residuals are standardized by the leverages but not by model variances. The fitted values are divided into nbins bins and the mean fitted value and mean squared residual is computed for each bin.

This function is similar in purpose to plotMeanVar but uses standardized residuals instead of pooled variances.

Value

Produces a mean-variance plot and returns a list with the following component:

mean numeric vector of average fitted values for bins

var numeric vector of the average squared residuals for bins

Author(s)

Davis McCarthy and Gordon Smyth

See Also

plotMeanVar, plotMDS.DGEList, plotSmear, plotMD.DGEList and plotBCV provide other ways to visualize DGE data.

Examples

# Example with Poisson data
log2mu <- seq(from=0,to=10,length=1000)
y <- matrix(rpois(4*1000,lambda=2^log2mu),1000,4)
binned <- plotMeanVar2(y)
abline(0,1)
plotQLDisp

Plot the quasi-likelihood dispersion

Description

Plot the genewise quasi-likelihood dispersion against the gene abundance (in log2 counts per million).

Usage

plotQLDisp(glmfit, xlab="Average Log2 CPM", ylab="Quarter-Root Mean Deviance", pch=16, cex=0.2, col.shrunk="red", col.trend="blue", col.raw="black", ...)

Arguments

- glmfit: a DGEGLM object produced by glmQLFit.
- xlab: label for the x-axis.
- ylab: label for the y-axis.
- pch: the plotting symbol. See points for more details.
- cex: plot symbol expansion factor. See points for more details.
- col.shrunk: color of the points representing the squeezed quasi-likelihood dispersions.
- col.trend: color of line showing dispersion trend.
- col.raw: color of points showing the unshrunk dispersions.
- ...: any other arguments are passed to plot.

Details

This function displays the quarter-root of the quasi-likelihood dispersions for all genes, before and after shrinkage towards a trend. If glmfit was constructed without an abundance trend, the function instead plots a horizontal line (of colour col.trend) at the common value towards which dispersions are shrunk. The quarter-root transformation is applied to improve visibility for dispersions around unity.

Value

A plot is created on the current graphics device.

Author(s)

Aaron Lun, Davis McCarthy, Gordon Smyth, Yunshun Chen.

References

Examples

```r
nbdisp <- 1/rchisq(1000, df=10)
y <- DGEList(matrix(rnbinom(6000, size = 1/nbdisp, mu = 10),1000,6))
design <- model.matrix(~factor(c(1,1,1,2,2,2)))
y <- estimateDisp(y, design)
fit <- glmQLFit(y, design)
plotQLDisp(fit)
fit <- glmQLFit(y, design, abundance.trend=FALSE)
plotQLDisp(fit)
```

Description

Make a mean-difference plot of two libraries of count data with smearing of points with very low counts, especially those that are zero for one of the columns.

Usage

```r
plotSmear(object, pair=NULL, de.tags=NULL, xlab="Average logCPM", ylab="logFC", pch=19, cex=0.2, smearWidth=0.5, panel.first=grid(), smooth.scatter=FALSE, lowess=FALSE, ...)
```

Arguments

- **object**: DGEList, DGEExact or DGELRT object containing data to produce an MA-plot.
- **pair**: pair of experimental conditions to plot (if NULL, the first two conditions are used). Ignored if object is a DGELRT object.
- **de.tags**: rownames for genes identified as being differentially expressed; use exactTest or glmLRT to identify DE genes. Note that ‘tag’ and ‘gene’ are synonymous here.
- **xlab**: x-label of plot
- **ylab**: y-label of plot
- **pch**: scalar or vector giving the character(s) to be used in the plot; default value of 19 gives a round point.
- **cex**: character expansion factor, numerical value giving the amount by which plotting text and symbols should be magnified relative to the default; default cex=0.2 to make the plotted points smaller
- **smearWidth**: width of the smear
- **panel.first**: an expression to be evaluated after the plot axes are set up but before any plotting takes place; the default grid() draws a background grid to aid interpretation of the plot
smooth.scatter logical, whether to produce a 'smooth scatter' plot using the KernSmooth::smoothScatter function or just a regular scatter plot; default is FALSE, i.e. produce a regular scatter plot

lowess logical, indicating whether or not to add a lowess curve to the MA-plot to give an indication of any trend in the log-fold change with log-concentration

... further arguments passed on to plot

Details

plotSmear produces a type of mean-difference plot (or MA plot) with a special representation (smearing) of log-ratios that are infinite. plotSmear resolves the problem of plotting genes that have a total count of zero for one of the groups by adding the 'smear' of points at low A value. The points to be smeared are identified as being equal to the minimum estimated concentration in one of the two groups. The smear is created by using random uniform numbers of width smearWidth to the left of the minimum A. plotSmear also allows easy highlighting of differentially expressed (DE) genes.

Value

Invisibly returns the x and y coordinates of the plotted points, and a plot is created on the current device.

Author(s)

Mark Robinson created the original concept of smearing the infinite log-fold-changes.

maPlot, plotMD.DGEList

Examples

```r
y <- matrix(rnbinom(10000, mu=5, size=2), ncol=4)
d <- DGEList(counts=y, group=rep(1:2, each=2), lib.size=colSums(y))
rownames(d$counts) <- paste("gene", 1:nrow(d$counts), sep=".")
d <- estimateCommonDisp(d)
plotSmear(d)

# find differential expression
de <- exactTest(d)

# highlighting the top 500 most DE genes
de.genes <- rownames(topTags(de, n=500)$table)
plotSmear(d, de.tags=de.genes)
```
plotSpliceDGE  Differential splicing plot

Description

Plot relative log-fold changes by exons for the specified gene and highlight the significantly spliced exons.

Usage

plotSpliceDGE(lrt, geneid=NULL, genecolname=NULL, rank=1L, FDR=0.05)

Arguments

lrt  DGELRT object produced by diffSpliceDGE.
geneid character string, ID of the gene to plot.
genecolname column name of lrt$genes containing gene IDs. Defaults to lrt$genecolname.
rank integer, if geneid=NULL then this ranked gene will be plotted.
FDR numeric, mark exons with false discovery rate less than this cutoff.

Details

Plot relative log2-fold-changes by exon for the specified gene. The relative logFC is the difference between the exon’s logFC and the overall logFC for the gene, as computed by diffSpliceDGE. The significantly spliced individual exons are highlighted as red dots. The size of the red dots are weighted by its significance.

Value

A plot is created on the current graphics device.

See Also

diffSpliceDGE, topSpliceDGE.
**predFC**

*Predictive log-fold changes*

**Description**

Computes estimated coefficients for a NB glm in such a way that the log-fold-changes are shrunk towards zero.

**Usage**

```r
## S3 method for class 'DGEList'
predFC(y, design, prior.count=0.125, offset=NULL, dispersion=NULL, weights=NULL, ...)
## S3 method for class 'SummarizedExperiment'
predFC(y, design, prior.count=0.125, offset=NULL, dispersion=NULL, weights=NULL, ...)
## Default S3 method:
predFC(y, design, prior.count=0.125, offset=NULL, dispersion=0, weights=NULL, ...)
```

**Arguments**

- `y`: a matrix of counts, or a DGEList object, or a SummarizedExperiment object
- `design`: the design matrix for the experiment
- `prior.count`: the average prior count to be added to each observation. Larger values produce more shrinkage.
- `offset`: numeric vector or matrix giving the offset in the log-linear model predictor, as for `glmFit`. Usually equal to log library sizes.
- `dispersion`: numeric vector of negative binomial dispersions.
- `weights`: optional numeric matrix giving observation weights
- `...`: other arguments are passed to `glmFit`.

**Details**

This function computes predictive log-fold changes (pfc) for a NB GLM. The pfc are posterior Bayesian estimators of the true log-fold-changes. They are predictive of values that might be replicated in a future experiment.

Specifically, the function adds a small prior count to each observation before fitting the GLM (see `addPriorCount` for details). The actual prior count that is added is proportion to the library size. This has the effect that any log-fold-change that was zero prior to augmentation remains zero and non-zero log-fold-changes are shrunk towards zero.

The prior counts can be viewed as equivalent to a prior belief that the log-fold changes are small, and the output can be viewed as posterior log-fold-changes from this Bayesian viewpoint. The output coefficients are called predictive log fold-changes because, depending on the prior, they may be a better prediction of the true log fold-changes than the raw estimates.
Log-fold changes for genes with low counts are shrunk more than those for genes with high counts. In particular, infinite log-fold-changes arising from zero counts are avoided. The exact degree to which this is done depends on the negative binomial dispersion.

Value

Numeric matrix of (shrunk) linear model coefficients on the log2 scale.

y <- DGEList(y, group=c(1,1,2,2))
design <- model.matrix(~group, data=y$samples)

# estimate the predictive log fold changes
predlfc <- predFC(y, design, dispersion=disp, prior.count=1)
logfc <- predFC(y, design, dispersion=disp, prior.count=0)
logfc.truncated <- pmax(pmin(logfc, 100), -100)

# plot predFC's vs logFC's
plot(predlfc[,2], logfc.truncated[,2],
    xlab="Predictive log fold changes", ylab="Raw log fold changes")
abline(a=0, b=1)
```

processAmplicons  
Process FASTQ files from pooled genetic sequencing screens

Description

Given a list of sample-specific index (barcode) sequences and hairpin/sgRNA-specific sequences from an amplicon sequencing screen, generate a DGEList of counts from the raw FASTQ files containing the sequence reads. The position of the index sequences and hairpin/sgRNA sequences is considered variable, with the hairpin/sgRNA sequences assumed to be located after the index sequences in the read.
Usage

processAmplicons(readfile, readfile2 = NULL, barcodefile, hairpinfile,
  allowMismatch = FALSE, barcodeMismatchBase = 1,
  hairpinMismatchBase = 2, dualIndexForwardRead = FALSE,
  verbose = FALSE, barcodesInHeader = FALSE,
  hairpinBeforeBarcode = FALSE, plotPositions = FALSE)

Arguments

readfile character vector giving one or more FASTQ filenames. Must be uncompressed text files.
readfile2 optional character vector giving one or more FASTQ filenames for reverse read. Must be uncompressed text files.
barcodefile filename containing sample-specific barcode IDs and sequences. File may be gzipped.
hairpinfile filename containing hairpin/sgRNA-specific IDs and sequences. File may be gzipped.
allowMismatch logical, indicates whether sequence mismatch is allowed.
barcodeMismatchBase maximum number of base sequence mismatches allowed in a barcode sequence when allowMismatch is TRUE.
hairpinMismatchBase maximum number of base sequence mismatches allowed in a hairpin/sgRNA sequence when allowMismatch is TRUE.
dualIndexForwardRead logical, indicates if forward reads contains a second barcode sequence (must be present in barcodefile) that should be matched.
verbose if TRUE, output program progress.
barcodesInHeader logical, indicates if barcode sequences should be matched in the header (sequence identifier) of each read (i.e. the first of every group of four lines in the FASTQ files).
hairpinBeforeBarcode logical, indicates that hairpin sequences appear before barcode sequences in each read. Setting this to TRUE will allow hairpins to exist anywhere in a read irrespective of barcode position. Leaving as FALSE will improve performance if hairpins are positioned after barcode sequences.
plotPositions logical, indicates if a density plot displaying the position of each barcode and hairpin/sgRNA sequence in the reads should be created. If dualIndexForwardRead is TRUE or readfile2 is not NULL, plotPositions will generate two density plots, side by side, indicating the positions of the first barcodes and hairpins in the first plot, and second barcodes in the second.
Details

The `processAmplicons` function allows for hairpins/sgRNAs/sample index sequences to be in variable positions within each read.

The input barcode file and hairpin/sgRNA files are tab-separated text files with at least two columns (named 'ID' and 'Sequences') containing the sample or hairpin/sgRNA IDs and a second column indicating the sample index or hairpin/sgRNA sequences to be matched. If `dualIndexForwardRead` is `TRUE`, a third column 'Sequences2' is expected in the barcode file. If `readfile2` is specified, another column 'SequencesReverse' is expected in the barcode file. The barcode file may also contain a 'group' column that indicates which experimental group a sample belongs to. Additional columns in each file will be included in the respective `$samples` or `$genes` data.frames of the final `DGEList` object. These files, along with the FASTQ files, are assumed to be in the current working directory.

To compute the count matrix, matching to the given barcodes and hairpins/sgRNAs is conducted in two rounds. The first round looks for an exact sequence match for the given barcode sequences and hairpin/sgRNA sequences through the entire read, returning the first match found. If a match isn’t found, the program performs a second round of matching which allows for sequence mismatches if `allowMismatch` is set to `TRUE`. The maximum number of mismatch bases in barcode and hairpin/sgRNA are specified by the parameters `barcodeMismatchBase` and `hairpinMismatchBase` respectively.

The program outputs a `DGEList` object, with a count matrix indicating the number of times each barcode and hairpin/sgRNA combination could be matched in reads from the input FASTQ files.

For further examples and data, refer to the case studies available from [https://bioinf.wehi.edu.au/shRNAseq/](https://bioinf.wehi.edu.au/shRNAseq/).

The argument `hairpinBeforeBarcode` was introduced in edgeR release version 3.38.2 and developmental version 3.39.3. Previously the function expected the sequences in the FASTQ files to have a fixed structure as per Figure 1A of Dai et al (2014). The revised function can process reads where the hairpins/sgRNAs/sample index sequences are in variable positions within each read. When `plotPositions=TRUE` a density plot of the match positions is created to allow the user to assess whether they occur in the expected positions.

Value

A `DGEList` object with following components:

- **counts**: read count matrix tallying up the number of reads with particular barcode and hairpin/sgRNA matches. Each row is a hairpin/sgRNA and each column is a sample.

- **genes**: In this case, hairpin/sgRNA-specific information (ID, sequences, corresponding target gene) may be recorded in this data.frame.

- **lib.size**: auto-calculated column sum of the counts matrix.

Note

This function replaced the earlier function `processHairpinReads` in edgeR 3.7.17.

q2qnbinom

Quantile to Quantile Mapping between Negative-Binomial Distributions

Description

Interpolated quantile to quantile mapping between negative-binomial distributions with the same dispersion but different means. The Poisson distribution is a special case.

Usage

q2pois(x, input.mean, output.mean)
q2qnbinom(x, input.mean, output.mean, dispersion=0)

Arguments

x numeric matrix of counts.
input.mean numeric matrix of population means for x. If a vector, then of the same length as nrow(x).
output.mean numeric matrix of population means for the output values. If a vector, then of the same length as nrow(x).
dispersion numeric scalar, vector or matrix giving negative binomial dispersion values.

Details

This function finds the quantile with the same left and right tail probabilities relative to the output mean as x has relative to the input mean. q2pois is equivalent to q2qnbinom with dispersion=0.

In principle, q2qnbinom gives similar results to calling pnbinom followed by qnbinom as in the example below. However this function avoids infinite values arising from rounding errors and does appropriate interpolation to return continuous values.

q2qnbinom is called by equalizeLibSizes to perform quantile-to-quantile normalization.

Value

numeric matrix of same dimensions as x, with output.mean as the new nominal population mean.

Author(s)

Gordon Smyth
See Also
equalizeLibSizes

Examples

```r
x <- 15
input.mean <- 10
output.mean <- 20
dispersion <- 0.1
q2qnbinom(x,input.mean,output.mean,dispersion)

# Similar in principle:
qnbinom(qnbinom(x,mu=input.mean,size=1/dispersion),mu=output.mean,size=1/dispersion)
```

read10X

**Read 10X Genomics Files**

**Description**
Reads 10X Genomics files containing single-cell RNA-seq UMI counts in Matrix Market format.

**Usage**

```r
read10X(mtx = NULL, genes = NULL, barcodes = NULL, path = ".", DGEList = TRUE)
```

**Arguments**

- **mtx**
  name of mtx file containing counts in Matrix Exchange Format. Defaults to matrix.mtx or matrix.mtx.gz.

- **genes**
  name of file containing gene IDs and names. Defaults to features.tsv or genes.tsv or gzipped versions of the same.

- **barcodes**
  optional name of file containing barcodes. Defaults to "barcodes.tsv" or barcodes.tsv.gz.

- **path**
  character string giving the directory containing the files. Defaults to the current working directory.

- **DGEList**
  logical. If TRUE, a DGEList will be returned, otherwise an unclassed list is returned.

**Details**
This function reads output files created by the 10X Genomics Cellranger pipeline, see [https://support.10xgenomics.com/single-cell-gene-expression/software/pipelines/latest/output/matrices](https://support.10xgenomics.com/single-cell-gene-expression/software/pipelines/latest/output/matrices). The UMI counts are assembled into an integer matrix in R with accompanying gene IDs and gene symbols. The results are returned as either a DGEList or an ordinary list.

The files mtx, genes and barcodes can be provided in either gzipped or unzipped versions.

This function creates an ordinary matrix of counts. To read the counts instead into a sparse matrix format, the read10xResults function in the scater package is an alternative.
readBismark2DGE

Read Bismark Coverage Files

Description

Read Bismark coverage files containing methylated and unmethylated read counts for CpG loci and create DGEList.

Usage

readBismark2DGE(files, sample.names=NULL, readr=TRUE, verbose=TRUE)
Arguments

files character vector of file names.
sample.names character vector of sample names. If NULL, sample names will be extracted from the file names.
readr logical. If TRUE, readr package is used to read the coverage files, otherwise read.delim is used.
verbose logical. If TRUE, read progress messages are send to standard output.

Details

This function reads tab-delimited coverage files output by Bismark software. Counts from multiple files are collated into a DGEList object.

Value

A DGEList object with a row for each unique genomic loci found in the files and two columns (containing methylated and unmethylated counts) for each sample.

Note

This function represents genomic loci as integers, so the largest locus position must be less than the maximum integer in R (about 2e9). The number of chromosomes times the largest locus position must be less than 1e16.

Author(s)

Gordon Smyth

References

Description

Reads and merges a set of text files containing gene expression counts.

Usage

readDGE(files, path=NULL, columns=c(1,2), group=NULL, labels=NULL, ...)
Arguments

- **files**: character vector of filenames, or a data.frame of sample information containing a column called `files`.
- **path**: character string giving the directory containing the files. Defaults to the current working directory.
- **columns**: numeric vector stating which columns of the input files contain the gene names and counts respectively.
- **group**: optional vector or factor indicating the experimental group to which each file belongs.
- **labels**: character vector giving short names to associate with the files. Defaults to the file names.
- **...**: other arguments are passed to `read.delim`.

Details

Each file is assumed to contain digital gene expression data for one genomic sample or count library, with gene identifiers in the first column and counts in the second column. Gene identifiers are assumed to be unique and not repeated in any one file. The function creates a combined table of counts with rows for genes and columns for samples. A count of zero will be entered for any gene that was not found in any particular sample.

By default, the files are assumed to be tab-delimited and to contain column headings. Other file formats can be handled by adding arguments to be passed to `read.delim`. For example, use `header=FALSE` if there are no column headings and use `sep=","` to read a comma-separated file.

Instead of being a vector, the argument `files` can be a data.frame containing all the necessary sample information. In that case, the filenames and group identifiers can be given as columns `files` and `group` respectively, and the `labels` can be given as the row.names of the data.frame.

Value

A `DGEList` object containing a matrix of counts, with a row for each unique tag found in the input files and a column for each input file.

Author(s)

Mark Robinson and Gordon Smyth

See `read.delim` for other possible arguments that can be accepted.

DGEList-class, DGEList.

Examples

```r
# Read all .txt files from current working directory

## Not run: files <- dir(pattern="*\.txt$")
RG <- readDGE(files)
## End(Not run)
```
**Description**

Rotation gene set testing for Negative Binomial generalized linear models.

**Usage**

```r
## S3 method for class 'DGEGLM'
roast(y, index = NULL, design = NULL, contrast = ncol(design), geneid = NULL,
      set.statistic = "mean", gene.weights = NULL, nrot = 1999, ...
## S3 method for class 'DGEGLM'
mroast(y, index = NULL, design = NULL, contrast = ncol(design), geneid = NULL,
       set.statistic = "mean", gene.weights = NULL, nrot = 1999,
       adjust.method = "BH", midp = TRUE, sort = "directional", ...)
```

**Arguments**

- **y** DGEGLM object.
- **index** index vector specifying which rows (probes) of `y` are in the test set. Can be a vector of integer indices, or a logical vector of length `nrow(y)`, or a vector of gene IDs corresponding to entries in `geneid`. Alternatively it can be a data.frame with the first column containing the index vector and the second column containing directional gene weights. For `mroast` or `fry`, index is a list of index vectors or a list of data.frames.
- **design** the design matrix. Defaults to `y$design`.
- **contrast** contrast for which the test is required. Can be an integer specifying a column of design, or the name of a column of design, or a numeric contrast vector of length equal to the number of columns of design.
- **geneid** gene identifiers corresponding to the rows of `y`. Can be either a vector of length `nrow(y)` or the name of the column of `y$genes` containing the gene identifiers. Defaults to `rownames(y)`.
- **set.statistic** summary set statistic. Possibilities are "mean","floormean","mean50" or "msq".
- **gene.weights** numeric vector of directional (positive or negative) genewise weights. For `mroast` or `fry`, this vector must have length equal to `nrow(y)`. For `roast`, can be of length `nrow(y)` or of length equal to the number of genes in the test set.
- **nrot** number of rotations used to compute the p-values.
- **adjust.method** method used to adjust the p-values for multiple testing. See `p.adjust` for possible values.
midp  logical, should mid-p-values be used in instead of ordinary p-values when adjusting for multiple testing?
sort  character, whether to sort output table by directional p-value ("directional"), non-directional p-value ("mixed"), or not at all ("none").

... other arguments are currently ignored.

Details

These functions perform self-contained gene set tests against the null hypothesis that none of the genes in the set are differentially expressed. fry is the recommended function in the edgeR context.

The roast gene set test was proposed by Wu et al (2010) for microarray data and the roast and mroast methods documented here extend the test to digital gene expression data. The roast method uses residual space rotations instead of permutations to obtain p-values, a technique that take advantage of the full generality of linear models. The negative binomial count data is converted to approximate normal deviates by computing mid-p quantile residuals (Dunn and Smyth, 1996; Routledge, 1994) under the null hypothesis that the contrast is zero, and the normal deviates are then passed to the limma roast function. See roast for more description of the test and for a complete list of possible arguments. mroast is similar but performs roast tests for multiple of gene sets instead of just one.

The fry method documented here similarly generalizes the fry gene set test for microarray data. fry is recommended over roast or mroast for count data because, in this context, it is equivalent to mroast but with an infinite number of rotations.

Value

roast produces an object of class Roast. See roast for details.
mroast and fry produce a data.frame. See mroast for details.

### roast.DGEList

**Self-contained Gene Set Tests for Digital Gene Expression Data**

**Description**

Rotation gene set testing for Negative Binomial generalized linear models.

**Usage**

```r
## S3 method for class 'DGEList'
fr(y, index = NULL, design = NULL, contrast = ncol(design), geneid = NULL,
    sort = "directional", ...)

## S3 method for class 'DGEList'
roast(y, index = NULL, design = NULL, contrast = ncol(design), geneid = NULL,
    set.statistic = "mean", gene.weights = NULL, nrot = 1999, ...)

## S3 method for class 'DGEList'
mroast(y, index = NULL, design = NULL, contrast = ncol(design), geneid = NULL,
    set.statistic = "mean", gene.weights = NULL, nrot = 1999,
    adjust.method = "BH", midp = TRUE, sort = "directional", ...)
```

**Arguments**

- `y` DGEList object.
index: index vector specifying which rows (probes) of y are in the test set. Can be a vector of integer indices, or a logical vector of length nrow(y), or a vector of gene IDs corresponding to entries in geneid. Alternatively it can be a data.frame with the first column containing the index vector and the second column containing directional gene weights. For mroast or fry, index is a list of index vectors or a list of data.frames.

design: the design matrix. Defaults to y$design or, failing that, to model.matrix(~y$samples$group).

contrast: contrast for which the test is required. Can be an integer specifying a column of design, or the name of a column of design, or a numeric contrast vector of length equal to the number of columns of design.

geneid: gene identifiers corresponding to the rows of y. Can be either a vector of length nrow(y) or the name of the column of y$genes containing the gene identifiers. Defaults to rownames(y).

set.statistic: summary set statistic. Possibilities are "mean", "floormean", "mean50" or "msq".

gene.weights: numeric vector of directional (positive or negative) genewise weights. For mroast or fry, this vector must have length equal to nrow(y). For roast, can be of length nrow(y) or of length equal to the number of genes in the test set.

nrot: number of rotations used to compute the p-values.

adjust.method: method used to adjust the p-values for multiple testing. See p.adjust for possible values.

midp: logical, should mid-p-values be used in instead of ordinary p-values when adjusting for multiple testing?

sort: character, whether to sort output table by directional p-value ("directional"), non-directional p-value ("mixed"), or not at all ("none").

...: other arguments are currently ignored.

Details

Examples
mu <- matrix(10, 100, 4)
group <- factor(c(0,0,1,1))
design <- model.matrix(~group)

# First set of 10 genes that are genuinely differentially expressed
iset1 <- 1:10
mu[iset1,3:4] <- mu[iset1,3:4]+10

# Second set of 10 genes are not DE
iset2 <- 11:20

# Generate counts and create a DGEList object
y <- matrix(rnbinom(100*4, mu=mu, size=10),100,4)
y <- DGEList(counts=y, group=group)

# Estimate dispersions
y <- estimateDisp(y, design)
roast(y, iset1, design, contrast=2)
mroast(y, iset1, design, contrast=2)
mroast(y, list(set1=iset1, set2=iset2), design, contrast=2)
Usage

```r
## S3 method for class 'DGEGLM'
romer(y, index, design=NULL, contrast=ncol(design), ...)
```

Arguments

- `y`:
  DGEGLM object.

- `index`:
  list of indices specifying the rows of `y` in the gene sets. The list can be made using `ids2indices`.

- `design`:
  design matrix. Defaults to `y$design`.

- `contrast`:
  contrast for which the test is required. Can be an integer specifying a column of `design`, or the name of a column of `design`, or else a contrast vector of length equal to the number of columns of `design`.

- `...`:
  other arguments are passed to `romer.default`. For example, the number of rotations `nrot` can be increased from the default of 9999 to increase the resolution of the p-values.

Details

The ROMER procedure described by Majewski et al (2010) is implemented in `romer` in the `limma` package. This `romer` method for `DGEGLM` objects makes the romer procedure available for count data such as RNA-seq data. The negative binomial count data is converted to approximate normal deviates by computing mid-p quantile residuals (Dunn and Smyth, 1996; Routledge, 1994) under the null hypothesis that the contrast is zero. The normal deviates are then passed to the `romer` function in `limma`. See `romer` for more description of the test and for a complete list of possible arguments.

Value

Numeric matrix giving p-values and the number of matched genes in each gene set. Rows correspond to gene sets. There are four columns giving the number of genes in the set and p-values for the alternative hypotheses up, down or mixed. See `romer` for details.

### romer.DGEList

**Rotation Gene Set Enrichment for Digital Gene Expression Data**

**Description**

Romer gene set enrichment tests for Negative Binomial generalized linear models.

**Usage**

```r
## S3 method for class 'DGEList'
romer(y, index, design=NULL, contrast=ncol(design), ...)
```

**Arguments**

- `y`: DGEList object.
- `index`: list of indices specifying the rows of `y` in the gene sets. The list can be made using `ids2indices`.
- `design`: design matrix. Defaults to `y$design` or, failing that, to `model.matrix(~y$samples$group)`.
- `contrast`: contrast for which the test is required. Can be an integer specifying a column of `design`, or the name of a column of `design`, or else a contrast vector of length equal to the number of columns of `design`.

**Examples**

```r
mu <- matrix(10, 100, 4)
group <- factor(c(0,0,1,1))
design <- model.matrix(~group)

# First set of 10 genes that are genuinely differentially expressed
iset1 <- 1:10
mu[iset1,3:4] <- mu[iset1,3:4]+20

# Second set of 10 genes are not DE
iset2 <- 11:20

# Generate counts and create a DGEList object
y <- matrix(rnbinom(100*4, mu=mu, size=10),100,4)
y <- DGEList(counts=y, group=group)

# Estimate dispersions
fit <- glmQLFit(y, design, legacy=FALSE)

romer(fit, iset1, design, contrast=2)
romer(fit, iset2, design, contrast=2)
romer(fit, list(set1=iset1, set2=iset2), design, contrast=2)
```
other arguments are passed to `romer.default`. For example, the number of rotations `nrot` can be increased from the default of 9999 to increase the resolution of the p-values.

Details

The ROMER procedure described by Majewski et al (2010) is implemented in `romer` in the limma package. This `romer` method for `DGEList` objects makes the romer procedure available for count data such as RNA-seq data. The negative binomial count data is converted to approximate normal deviates by computing mid-p quantile residuals (Dunn and Smyth, 1996; Routledge, 1994) under the null hypothesis that the contrast is zero. The normal deviates are then passed to the `romer` function in limma. See `romer` for more description of the test and for a complete list of possible arguments.

---

**rowsum**  

**Sum Over Groups of Genes**

**Description**

Condense the rows of a DGEList object so that counts are summed over specified groups of genes.

**Usage**

```r
## S3 method for class 'DGEList'
rowsum(x, group, reorder=FALSE, na.rm=FALSE, ...)
## S3 method for class 'SummarizedExperiment'
rowsum(x, group, reorder=FALSE, na.rm=FALSE, ...)
```

**Arguments**

- `x`: a DGEList object or a SummarizedExperiment object
- `group`: a vector or factor giving the grouping, with one element per row of `x`. Missing values will be treated as another group and a warning will be given.
- `reorder`: if TRUE, then the row.names of the resulting DGEList will be in order of `sort(unique(group))`, if FALSE, they will be in the order that groups were encountered.
- `na.rm`: logical (TRUE or FALSE). Should NA (including NaN) values be discarded?
- `...`: other arguments are not currently used

**Details**

If `x` is a SummarizedExperiment object, it is first converted into a DGEList object.

A new DGEList object is computed, with the same columns as `x`, but for which the rows correspond to the unique values of `group`. The counts for rows with the same group value are summed.

Columns of `x$genes` will be retained in the output if they contain group-level annotation. Columns that vary within groups will be dropped.
Value

DGEList object with the same number of columns as x and rows corresponding to the unique values of group.

Author(s)

Gordon Smyth

See Also

rowsum in the base package.

Examples

```r
x <- DGEList(counts=matrix(1:8,4,2))
rowsum(x, group=c("A","A","B","B"))
```

---

scaleOffset  Scale offsets

Description

Ensures scale of offsets are consistent with library sizes.

Usage

```r
## S3 method for class 'DGEList'
scaleOffset(y, offset, ...)
## Default S3 method:
scaleOffset(y, offset, ...)
```

Arguments

- `y` numeric vector or matrix of counts, or a DGEList object.
- `offset` numeric vector or matrix of offsets to be scaled. If a vector, its length must equal to the length of y or the number of columns of y. If a matrix, its dimension must equal to the dimension of y.
- `...` other arguments that are not currently used.

Details

scaleOffset ensures that the scale of offsets are consistent with library sizes. This is done by ensuring that the mean offset for each gene is the same as the mean log-library size. The length or dimensions of offset should be consistent with the number of libraries in y.
Value
scaleOffset.default returns a numeric vector if offset is a vector, a matrix if offset is a matrix or a CompressedMatrix object if offset is a CompressedMatrix. scaleOffset.DGEList computes the scaled offsets and store them in the offset component of the input DGEList object.

Author(s)
Aaron Lun, Yunshun Chen

Examples
y <- matrix(rnbinom(40,size=1,mu=100),10,4)
offset <- rnorm(4)
scaleOffset(y, offset)

---

SE2DGEList

SummarizedExperiment to DGEList

Description
Given any SummarizedExperiment data object, extract basic information needed and convert it into a DGEList object.

Usage
SE2DGEList(object)

Arguments
object a SummarizedExperiment object. Must have counts in its assay component.

Details
This function takes a SummarizedExperiment data object as input. The counts of the assay component of the input SummarizedExperiment data object is extracted and used as the counts component of the output DGEList object. The rowRanges or rowData of the input is converted into a data.frame and used as genes in the output. The colData of the input is also converted into a data.frame and used as the sample information in the output.

Value
A DGEList object.

Author(s)
Yunshun Chen and Gordon Smyth
Seurat2PB

Examples

## Not run:
library(SummarizedExperiment)
example(SummarizedExperiment)
y <- SE2DGEList(se)
## End(Not run)

Description

Given a Seurat or SeuratObject data object, create pseudo-bulk samples using the sample and cluster information and return a DGEList object.

Usage

Seurat2PB(object, sample, cluster="seurat_clusters")

Arguments

- **object**: a Seurat or SeuratObject class data object. Must have counts in its RNA assay.
- **sample**: character specifying the column of object@meta.data that contains sample information of the single cell data. Must be one of the column names of object@meta.data.
- **cluster**: character specifying the column of object@meta.data that contains single cell cluster information. Must be one of the column names of object@meta.data. Default to seurat_clusters.

Details

This function takes a Seurat or SeuratObject data object as input. It is assumed that the input data object contains raw RNA-seq read counts of multiple samples as well as cell clustering information (usually from a single cell integration analysis). The counts of the RNA assay of the input data object is first extracted. A pseudo-bulk count matrix is formed by aggregating the read counts of all the cells within the same cluster for each sample. The pseudo-bulk count matrix is then used as the counts component of the output DGEList object. The cluster and sample information of the pseudo-bulk counts is stored in the samples component. The row names of the input data object, together with other extra feature information (if any) found in the input, are stored in the genes component.

Value

A DGEList object.

Author(s)

Yunshun Chen
Examples

```r
## Not run:
ngenes <- 1e3
ncells <- 1e3
sp <- paste0("sample", sample(1:2, ncells, replace=TRUE))
clst <- sample(1:3, ncells, replace=TRUE)

counts <- matrix(rnbinom(ngenes*ncells, mu=10, size=2), ngenes, ncells)
colnames(counts) <- paste0("Cell",1:ncells)
rownames(counts) <- paste0("Gene",1:ngenes)
so <- CreateSeuratObject(counts = counts)
so@meta.data <- cbind(so@meta.data, sample=sp, cluster=clst)

y <- Seurat2PB(so, sample="sample", cluster="cluster")

## End(Not run)
```

spliceVariants  Identify Genes with Splice Variants

Description

Identify genes exhibiting evidence for splice variants (alternative exon usage/transcript isoforms) from exon-level count data using negative binomial generalized linear models.

Usage

```r
spliceVariants(y, geneID, dispersion=NULL, group=NULL, estimate.genewise.disp=TRUE, trace=FALSE)
```

Arguments

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>y</code></td>
<td>either a matrix of exon-level counts or a DGEList object with (at least) elements counts (table of counts summarized at the exon level) and samples (data frame containing information about experimental group, library size and normalization factor for the library size). Each row of <code>y</code> should represent one exon.</td>
</tr>
<tr>
<td><code>geneID</code></td>
<td>vector of length equal to the number of rows of <code>y</code>, which provides the gene identifier for each exon in <code>y</code>. These identifiers are used to group the relevant exons into genes for the gene-level analysis of splice variation.</td>
</tr>
<tr>
<td><code>dispersion</code></td>
<td>scalar (in future a vector will also be allowed) supplying the negative binomial dispersion parameter to be used in the negative binomial generalized linear model.</td>
</tr>
<tr>
<td><code>group</code></td>
<td>factor supplying the experimental group/condition to which each sample (column of <code>y</code>) belongs. If <code>NULL</code> (default) the function will try to extract if from <code>y</code>, which only works if <code>y</code> is a DGEList object.</td>
</tr>
</tbody>
</table>
spliceVariants

estimate.genewise.disp
   logical, should genewise dispersions (as opposed to a common dispersion value) be computed if the dispersion argument is NULL?

trace
   logical, whether or not verbose comments should be printed as function is run. Default is FALSE.

Details

This function can be used to identify genes showing evidence of splice variation (i.e. alternative splicing, alternative exon usage, transcript isoforms). A negative binomial generalized linear model is used to assess evidence, for each gene, given the counts for the exons for each gene, by fitting a model with an interaction between exon and experimental group and comparing this model (using a likelihood ratio test) to a null model which does not contain the interaction. Genes that show significant evidence for an interaction between exon and experimental group by definition show evidence for splice variation, as this indicates that the observed differences between the exon counts between the different experimental groups cannot be explained by consistent differential expression of the gene across all exons. The function topTags can be used to display the results of spliceVariants with genes ranked by evidence for splice variation.

Value

spliceVariants returns a DGEExact object, which contains a table of results for the test of differential splicing between experimental groups (alternative exon usage), a data frame containing the gene identifiers for which results were obtained and the dispersion estimate(s) used in the statistical models and testing.

Author(s)

Davis McCarthy, Gordon Smyth

See Also

estimateExonGenewiseDisp for more information about estimating genewise dispersion values from exon-level counts. DGEList for more information about the DGEList class. topTags for more information on displaying ranked results from spliceVariants. estimateCommonDisp and related functions for estimating the dispersion parameter for the negative binomial model.

Examples

# generate exon counts from NB, create list object
y<-matrix(rnbinom(40, size=1, mu=10), nrow=10)
d<-DGEList(counts=y, group=rep(1:2, each=2))
genes <- rep(c("gene.1", "gene.2"), each=5)
disp <- 0.2
spliceVariants(d, genes, disp)
**splitIntoGroups**

**Split the Counts or Pseudocounts from a DGEList Object According To Group**

### Description

Split the counts from a DGEList object according to group, creating a list where each element consists of a numeric matrix of counts for a particular experimental group. Given a pair of groups, split pseudocounts for these groups, creating a list where each element is a matrix of pseudocounts for a particular group.

### Usage

#### S3 method for class 'DGEList'

```r
splitIntoGroups(y, ...)
```

#### Default S3 method:

```r
splitIntoGroups(y, group=NULL, ...)
```

```r
splitIntoGroupsPseudo(pseudo, group, pair)
```

### Arguments

- **y** matrix of counts or a DGEList object.
- **group** vector or factor giving the experimental group/condition for each library.
- **pseudo** numeric matrix of quantile-adjusted pseudocounts to be split
- **pair** vector of length two stating pair of groups to be split for the pseudocounts
- **...** other arguments that are not currently used.

### Value

- `splitIntoGroups` outputs a list in which each element is a matrix of count counts for an individual group. `splitIntoGroupsPseudo` outputs a list with two elements, in which each element is a numeric matrix of (pseudo-)count data for one of the groups specified.

### Author(s)

Davis McCarthy

### Examples

```r
# generate raw counts from NB, create list object
y <- matrix(rnbinom(80, size=1, mu=10), nrow=20)
d <- DGEList(counts=y, group=rep(1:2, each=2), lib.size=rep(c(1000:1001), 2))
rownames(d$counts) <- paste("gene", 1:nrow(d$counts), sep=".")
z1 <- splitIntoGroups(d)
z2 <- splitIntoGroupsPseudo(d$counts, d$group, pair=c(1,2))
```
Subset DGEList, DGEGLM, DGEExact and DGELRT Objects

Description

Extract a subset of a DGEList, DGEGLM, DGEExact or DGELRT object.

Usage

```r
## S3 method for class 'DGEList'
object[i, j, keep.lib.sizes=TRUE]
## S3 method for class 'DGEGLM'
object[i, j]
## S3 method for class 'DGEExact'
object[i, j]
## S3 method for class 'DGELRT'
object[i, j]
## S3 method for class 'TopTags'
object[i, j]
```

Arguments

- `object`: object of class DGEList, DGEGLM, DGEExact or DGELRT. For subsetListOfArrays, any list of conformal matrices and vectors.
- `i,j`: elements to extract. `i` subsets the genes while `j` subsets the libraries. Note that columns of DGEGLM, DGEExact and DGELRT objects cannot be subsetted.
- `keep.lib.sizes`: logical, if TRUE the lib.sizes will be kept unchanged on output, otherwise they will be recomputed as the column sums of the counts of the remaining rows.

Details

`i,j` may take any values acceptable for the matrix components of object of class DGEList. See the `Extract` help entry for more details on subsetting matrices. For DGEGLM, DGEExact and DGELRT objects, only rows (i.e. `i`) may be subsetted.

Value

An object of the same class as `object` holding data from the specified subset of rows and columns.

Author(s)

Davis McCarthy, Gordon Smyth

See Also

`Extract` in the base package.
Examples

d <- matrix(rnbinom(16, size=1, mu=10), 4, 4)
rownames(d) <- c("a", "b", "c", "d")
colnames(d) <- c("A1", "A2", "B1", "B2")
d <- DGEList(counts=d, group=factor(c("A", "A", "B", "B")))
d[1:2,]
d[1:2,2]
d[,]2
results <- exactTest(d)
results[1:2,]
# NB: cannot subset columns for DGEExact objects

sumTechReps

Sum Over Replicate Samples

Description

Condense the columns of a matrix or DGEList object so that counts are summed over technical replicate samples.

Usage

## Default S3 method:
sumTechReps(x, ID=colnames(x), ...)
## S3 method for class 'DGEList'
sumTechReps(x, ID=colnames(x), ...)
## S3 method for class 'SummarizedExperiment'
sumTechReps(x, ID, ...)

Arguments

x a numeric matrix or DGEList object.
ID sample identifier.
... other arguments are not currently used.

Details

A new matrix or DGEList object is computed in which the counts for technical replicate samples are replaced by their sums.

Value

A data object of the same class as x with a column for each unique value of ID. For a SummarizedExperiment object, it is converted into a DGEList object. Columns are in the same order as the ID values first occur in the ID vector.
systematicSubset

Description

Take a systematic subset of indices stratified by a ranking variable.

Usage

systematicSubset(n, order.by)

Arguments

n integer giving the size of the subset.
order.by numeric vector of the values by which the indices are ordered.

Value

systematicSubset returns a vector of size n.

Author(s)

Gordon Smyth

See Also

order

Examples

y <- rnorm(100, 1, 1)
systematicSubset(20, y)
thinCounts  

Binomial or Multinomial Thinning of Counts

Description

Reduce the size of Poisson-like counts by binomial thinning.

Usage

thinCounts(x, prob=NULL, target.size=min(colSums(x)))

Arguments

- **x**: numeric vector or array of non-negative integers.
- **prob**: numeric scalar or vector of same length as x, the expected proportion of the events to keep.
- **target.size**: integer scale or vector of the same length as NCOL(x), the desired total column counts. Must be not greater than column sum of x. Ignored if prob is not NULL.

Details

If prob is not NULL, then this function calls rbinom with size=x and prob=prob to generate the new counts. This is classic binomial thinning. The new column sums are random, with expected values determined by prob.

If prob is NULL, then this function does multinomial thinning of the counts to achieve specified column totals. The default behavior is to thin the columns to have the same column sum, equal to the smallest column sum of x.

If the elements of x are Poisson, then binomial thinning produces new Poisson random variables with expected values reduced by factor prob. If the elements of each column of x are multinomial, then multinomial thinning produces a new multinomial observation with a reduced sum.

Value

A vector or array of the same dimensions as x, with thinned counts.

Author(s)

Gordon Smyth

Examples

x <- rpois(10, lambda=10)
thinCounts(x, prob=0.5)
**topSpliceDGE**  
*Top table of differentially spliced genes or exons*

---

**Description**

Top table ranking the most differentially spliced genes or exons.

**Usage**

```r
topSpliceDGE(lrt, test="Simes", number=10, FDR=1)
```

**Arguments**

- `lrt`  
  DGELRT object produced by `diffSpliceDGE`.
- `test`  
  character string, possible values are "Simes", "gene" or "exon". "exon" gives exon-level tests for each exon. "gene" gives gene-level tests for each gene. "Simes" gives genewise p-values derived from the exon-level tests after Simes adjustment for each gene.
- `number`  
  integer, maximum number of rows to output.
- `FDR`  
  numeric, only show exons or genes with false discovery rate less than this cutoff.

**Details**

Ranks genes or exons by evidence for differential splicing. The exon-level tests test for differences between each exon and all the exons for the same gene. The gene-level tests test for any differences in exon usage between experimental conditions.

The Simes method processes the exon-level p-values to give an overall call of differential splicing for each gene. It returns the minimum Simes-adjusted p-values for each gene.

The gene-level tests are likely to be powerful for genes in which several exons are differentially splices. The Simes p-values is likely to be more powerful when only a minority of the exons for a gene are differentially spliced. The exon-level tests are not recommended for formal error rate control.

**Value**

A data.frame with any annotation columns found in `lrt` plus the following columns:

- **NExons**  
  number of exons if `test="Simes"` or "gene"
- **Gene.Exon**  
  exon annotation if `test="exon"`
- **logFC**  
  log-fold change of one exon vs all the exons for the same gene (if `test="exon"`)  
- **exon.LR**  
  LR-statistics for exons (if `test="exon"` and the object for `diffSpliceDGE` was produced by `glmFit`)
- **exon.F**  
  F-statistics for exons (if `test="exon"` and the object for `diffSpliceDGE` was produced by `glmQLFit`)
gene.LR  LR-statistics for genes (if test="gene" and the object for diffSpliceDGE was produced by glmFit)
gene.F  F-statistics for genes (if test="gene" and the object for diffSpliceDGE was produced by glmQLFit)
P.Value  p-value
FDR  false discovery rate

**Table of the Top Differentially Expressed Genes/Tags**

**Description**
Extracts the most differentially expressed genes (or sequence tags) from a test object, ranked either by p-value or by absolute log-fold-change.

**Usage**
```
topTags(object, n = 10, adjust.method = "BH", sort.by = "PValue", p.value = 1)
```

**Arguments**
- **object**: a `DGEEexact` or `DGELRT` object containing test statistics and p-values. Usually created by `exactTest`, `glmLRT`, `glmTreat` or `glmQLFit`.
- **n**: integer, maximum number of genes/tags to return.
- **adjust.method**: character string specifying the method used to adjust p-values for multiple testing. See `p.adjust` for possible values.
- **sort.by**: character string specifying the sort method. Possibilities are "PValue" for p-value, "logFC" for absolute log-fold change or "none" for no sorting.
- **p.value**: numeric cutoff value for adjusted p-values. Only tags with adjusted p-values equal or lower than specified are returned.
Details

This function is closely analogous to the `topTable` function in the limma package. It accepts a test statistic object created by any of the edgeR functions `exactTest`, `glmLRT`, `glmTreat` or `glmQLFTest` and extracts a readable data.frame of the most differentially expressed genes. The data.frame collates the annotation and differential expression statistics for the top genes. The data.frame is wrapped in a TopTags output object that records the test statistic used and the multiple testing adjustment method.

TopTags objects will return dimensions and hence functions such as `dim`, `nrow` or `ncol` are defined on them. TopTags objects also have a `show` method so that printing produces a compact summary of their contents.

topTags permits ranking by fold-change but the authors do not recommend fold-change ranking or fold-change cutoffs for routine RNA-seq analysis. The p-value ranking is intended to more biologically meaningful, especially if the p-values were computed using `glmTreat`.

Value

An object of class `TopTags`, which is a list-based class with the following components:

table  a data.frame containing differential expression results for the top genes in sorted order. The number of rows is the smaller of `n` and the number of genes with adjusted p-value less than or equal to `p.value`. The data.frame includes all the annotation columns from `object$genes` and all statistic columns from `object$table` plus one of:

FDR: false discovery rate (only when `adjust.method` is "BH", "BY" or "fdr")
FWER: family-wise error rate (only when `adjust.method` is "holm", "hochberg", "hommel" or "bonferroni").

adjust.method character string specifying the method used to adjust p-values for multiple testing, same as input argument.

comparison character vector giving the names of the two groups being compared (for DGEExact objects) or the glm contrast being tested (for DGELRT objects).

test character string stating the name of the test.

Note

The terms ‘tag’ and ‘gene’ are used synonymously on this page and refer to the rows of `object`. In general, the rows might be genes, sequence tags, transcripts, exons or whatever type of genomic feature is appropriate for the analysis at hand.

`exactTest`, `glmLRT`, `glmTreat`, `glmQLFTest`, `dim.TopTags`, `p.adjust`.

Examples

```r
# generate raw counts from NB, create list object
y <- matrix(rnbinom(80, size=1, mu=10), nrow=20)
d <- DGEList(counts=y, group=rep(1:2, each=2), lib.size=rep(c(1000:1001),2))
rownames(d$counts) <- paste("gene", 1:nrow(d$counts), sep=".")

# estimate common dispersion and find differences in expression
# here we demonstrate the 'exact' methods, but the use of topTags is
# the same for a GLM analysis
d <- estimateCommonDisp(d)
d <- exactTest(d)

d <- exactTest(d)

topTags(de)

tp <- topTags(de, n=15)

topTags(de, sort.by="logFC")
```

validDGEList

**Check for Valid DGEList object**

Description

Check for existence of standard components of DGEList object.

Usage

`validDGEList(y)`

Arguments

- `y` DGEList object.
Details

This function checks that the standard counts and samples components of a DGEList object are present.

Value

DGEList with missing components added.

Author(s)

Gordon Smyth

See Also

DGEList

Examples

counts <- matrix(rpois(4*2,lambda=5),4,2)
dge <- new("DGEList", list(counts=counts))
validDGEList(dge)

voomLmFit

Apply voom-lmFit Pipeline While Accounting for Loss of Residual DF Due to Exact Zeros

Description

Transform count data to log2-counts per million (logCPM), estimate voom precision weights and fit limma linear models while allowing for loss of residual degrees of freedom due to exact zeros.

Usage

voomLmFit(counts, design = NULL, block = NULL, prior.weights = NULL,
sample.weights = FALSE, var.design = NULL, var.group = NULL,
lib.size = NULL, normalize.method = "none",
span = 0.5, plot = FALSE, save.plot = FALSE, keep.EList = TRUE)

Arguments

counts a numeric matrix containing raw counts, or an ExpressionSet containing raw counts, or a DGEList object. Counts must be non-negative and NAs are not permitted.
design design matrix with rows corresponding to samples and columns to coefficients to be estimated. Defaults to the unit vector meaning that samples are treated as replicates.
block vector or factor specifying a blocking variable on the samples. Has length equal to ncol(counts). Samples within each block are assumed to be correlated.
prior.weights prior weights. Can be a numeric matrix of individual weights of same dimensions as the counts, or a numeric vector of sample weights with length equal to ncol(counts), or a numeric vector of gene weights with length equal to nrow(counts).

sample.weights logical value, if TRUE then empirical sample quality weights will be estimated.

var.design optional design matrix for the sample weights. Defaults to the sample-specific model whereby each sample has a distinct variance.

var.group optional vector or factor indicating groups to have different array weights. This is another way to specify var.design for groupwise sample weights.

lib.size numeric vector containing total library sizes for each sample. Defaults to the normalized (effective) library sizes in counts if counts is a DGEList or to the columnwise count totals if counts is a matrix.

normalize.method the microarray-style normalization method to be applied to the logCPM values (if any). Choices are as for the method argument of normalizeBetweenArrays when the data is single-channel. Any normalization factors found in counts will still be used even if normalize.method="none".

span width of the smoothing window used for the lowess mean-variance trend. Expressed as a proportion between 0 and 1.

plot logical, should a plot of the mean-variance trend be displayed?

save.plot logical, should the coordinates and line of the plot be saved in the output?

keep.EList logical. If TRUE, then the normalized log2-CPM values and voom weights will be saved in the component EList of the output object.

Details

This function adapts the limma voom method (Law et al, 2014) to allow for loss of residual degrees of freedom due to exact zero counts (Lun and Smyth, 2017). The loss residual df occurs when all the counts in a group are zero or when there are blocking factors that can fit zero counts exactly. The function transforms the counts to the log2-CPM scale, computes voom precision weights and fits limma linear models. Residual df are computed similarly as far glmQLFit.

The function is analogous to calling voom followed by duplicateCorrelation and lmFit except for the modified residual df values and residual standard deviation sigma values. This function returns df.residual values that are less than or equal to those from lmFit and sigma values that are greater than or equal to those from lmFit. voomLmFit is more robust to zero counts than calling voom, duplicateCorrelation and lmFit separately and provides more rigorous error rate control.

If block is specified, then the intra-block correlation is estimated using duplicateCorrelation. In that case, the voom weights and the intra-block correlation are each estimated twice to achieve effective convergence.

Empirical sample quality weights will be estimated if sample.weights=TRUE or if var.design or var.group are non-NULL (Liu et al 2015). In that case, voomLmFit is analogous to running voomWithQualityWeights followed by lmFit.

voomLmFit is usually followed by running eBayes on the fitted model object.
weightedCondLogLikDerDelta

Weighted Conditional Log-Likelihood in Terms of Delta

Description

Weighted conditional log-likelihood parameterized in terms of delta (\(\phi / (\phi+1)\)) for a given gene, maximized to find the smoothed (moderated) estimate of the dispersion parameter

Usage

\[
\text{weightedCondLogLikDerDelta}(y, \text{delta}, \text{tag}, \text{prior.n}=10, \text{ntags}=\text{nrow}(y[[1]]), \text{der}=0)
\]
Arguments

- **y**: list with elements comprising the matrices of count data (or pseudocounts) for the different groups
- **delta**: parameter of negative binomial
- **tag**: gene at which the weighted conditional log-likelihood is evaluated
- **prior.n**: smoothing parameter that indicates the weight to put on the common likelihood compared to the individual gene’s likelihood; default 10 means that the common likelihood is given 10 times the weight of the individual gene’s likelihood in the estimation of the genewise dispersion
- **ntags**: numeric scalar number of genes in the dataset to be analysed
- **der**: derivative, either 0 (the function), 1 (first derivative) or 2 (second derivative)

Details

This function computes the weighted conditional log-likelihood for a given gene, parameterized in terms of delta. The value of delta that maximizes the weighted conditional log-likelihood is converted back to the phi scale, and this value is the estimate of the smoothed (moderated) dispersion parameter for that particular gene. The delta scale for convenience (delta is bounded between 0 and 1). Users should note that ‘tag’ and ‘gene’ are synonymous when interpreting the names of the arguments for this function.

Value
	numeric scalar of function/derivative evaluated for the given gene and delta

Author(s)

Mark Robinson, Davis McCarthy

Examples

counts<-matrix(rnbinom(20,size=1,mu=10),nrow=5)
d<-DGEList(counts=counts,group=rep(1:2,each=2),lib.size=rep(c(1000:1001),2))
y<-splitIntoGroups(d)
ll1<-weightedCondLogLikDerDelta(y,delta=0.5,tag=1,prior.n=10,der=0)
ll2<-weightedCondLogLikDerDelta(y,delta=0.5,tag=1,prior.n=10,der=1)

---

WLEB

*Weighted Likelhood Empirical Bayes*

Description

Compute empirical Bayes moderated parameter estimators using a weighted likelihood approach.
Usage

```r
WLEB(theta, loglik, prior.n = 5, covariate = NULL, trend.method = "locfit", span = NULL,
overall = TRUE, trend = TRUE, individual = TRUE, m0 = NULL, m0.out = FALSE)
```

Arguments

- `theta` numeric vector of values of the parameter at which the log-likelihoods are calculated.
- `loglik` numeric matrix of log-likelihood of all the candidates at those values of parameter.
- `prior.n` numeric scaler, estimate of the prior weight, i.e. the smoothing parameter that indicates the weight to put on the common likelihood compared to the individual’s likelihood.
- `covariate` numeric vector of values across which a parameter trend is fitted
- `trend.method` method for estimating the parameter trend. Possible values are "none", "movingave", "loess", "locfit" or "locfit.mixed". The latter options cause movingAverageByCol(), loessBycol() and locfitByCol() respectively to be called to smooth loglik by the covariate values. The "locfit.mixed" method is the same as "locfit" but uses a polynomial of degree 1 for lowly expressed genes.
- `span` width of the smoothing window, as a proportion of the data set.
- `overall` logical, should a single value of the parameter which maximizes the sum of all the log-likelihoods be estimated?
- `trend` logical, should a parameter trend (against the covariate) which maximizes the local shared log-likelihoods be estimated?
- `individual` logical, should individual estimates of all the candidates after applying empirical Bayes method along the trend be estimated?
- `m0` numeric matrix of local shared log-likelihoods. If NULL, it will be calculated using the method selected by trend.method.
- `m0.out` logical, should local shared log-likelihoods be included in the output?

Details

This function implements a very general empirical Bayes strategy outlined by McCarthy et al (2012). McCarthy et al used the method to estimate genewise negative binomial dispersion parameters, but here the method is generalized to apply to any parameter and any likelihood function. The method gives similar results to parametric empirical Bayes with a conjugate prior, when a conjugate prior exists, but does not require the prior distribution to be specified. The prior distribution is instead inferred from the pooled likelihood, i.e., from the likelihood that would arise from pooling all the cases or from pooling all the cases with similar covariate values.

The function assumes a series of cases. Each case leads to data set from which a parameter (theta) is to be estimated. For each case, the log-likelihood function has been evaluated over a grid of possible values for theta. The function takes as input the matrix of log-likelihood values where the rows correspond to cases and the columns correspond to putative parameter values.

Each case is associated with a covariate value that might affect theta. The "overall" parameter estimate is the maximum likelihood estimator of theta that arises if the likelihood is averaged over
cases and then maximized over theta. The "trend" parameter estimates are estimates for theta that arise if each column of loglik is replaced by a smooth trend with respect to the covariate. The "individual" parameter estimate for each case is a compromise between the maximum likelihood estimate for that case alone and a global parameter estimate computed from all the cases, the latter being either the overall estimate (if trend.method="none" or the trend estimate (otherwise).

Value

A list with the following:

overall the parameter estimate that maximizes the sum of all the log-likelihoods.
trend the estimated trended parameters against the covariate.
individual the individual estimates of all the candidates after applying empirical Bayes method along the trend.
shared.loglik the estimated numeric matrix of local shared log-likelihoods

locfitByCol, movingAverageByCol and loessByCol implement the local fit, moving average or loess smoothers.

Examples

```r
y <- matrix(rpois(100, lambda=10), ncol=4)
theta <- 7:14
loglik <- matrix(0,nrow=nrow(y),ncol=length(theta))
for(i in 1:nrow(y))
  for(j in 1:length(theta))
    loglik[i,j] <- sum(dpois(y[i,], theta[j] ,log=TRUE))
covariate <- log(rowSums(y))
out <- WLEB(theta, loglik, prior.n=3, covariate)
out
```
Z-score Equivalents of Negative Binomial Deviate

Description

Compute z-score equivalents of negative binomial random deviates.

Usage

zscoreNBinom(q, size, mu, method = "midp")

Arguments

- `q`: numeric vector or matrix of non-negative quantiles.
- `size`: numeric vector of non-negative size parameters.
- `mu`: numeric vector of means.
- `method`: method for converting from discrete to continuous distribution. Possible values are "midp" or "random".

Details

The mid-p method (method="midp") applies a continuity correction by splitting the probability mass of each integer in two. It computes the mid-p tail probability of q, then converts to the standard normal deviate with the same cumulative probability distribution value. Care is taken to do the computations accurately in both tails of the distributions.

The randomized method (method="random") computes randomized quantile residuals (Dunn and Smyth, 1996). In this method, the tail probabilities are randomized over the possible values covered by the discrete integer counts. If q follows a negative binomial distribution with the size and mean correctly specified, then the z-values generated by the randomized method are exactly standard normal.

Non-integer values of q are allowed. The mid-p method handles non-integer values by interpolation while the randomized method rounds q to integers.

Value

Numeric vector or matrix giving equivalent quantiles from the standard normal distribution.
